KEY TERMS

Artificial Neural Network: Structure composes of a group of interconnected artificial neurons or units. The objective of a NN is to transform the inputs into meaningful outputs.

Correlation-based Feature Selection: Feature Selection^(*) algorithm which heuristic measures the correlation between attributes and rewards those feature subsets in which each feature is highly correlated with the class and uncorrelated with other subset features.

^(*)**Feature Selection:** Process, commonly used in machine learning, of identifying and removing as much of the irrelevant and redundant information as possible.

Feature Space: n -dimensional space where each example (pattern) is represented as a point. The dimension of this space is equal to the number of features used to describe the patterns.

Field Programmable Array (FPGA): A FPGA is an integrated circuit that can be programmed in the field after manufacture.

K-Cross-Validation: Method to estimate the accuracy of a classifier system. In this approach, the dataset, D , is randomly split into K mutually exclusive subsets (folds) of equal size (D_1, D_2, \dots, D_k) and K classifiers are built. The i -th classifier is trained on the union of all $D_j / j \neq i$ and tested on D_i . The estimate accuracy is the overall number of correct classifications divided by the number of instances in the dataset.

Machine Learning: Computer Scientific field focused on the design, analysis and implementation, of algorithms that learn from experience.

One Against All: Approach to solve multi-class classification problems which creates one binary problem for each of the K classes. The classifier for class i is trained to distinguish examples in class i from all other examples.

Weka: Collection of machine learning algorithms for solving data mining problems implemented in Java and open sourced under the GPL.

Ensemble of SVM Classifiers for Spam Filtering

Ángela Blanco

Universidad Pontificia de Salamanca, Spain

Manuel Martín-Merino

Universidad Pontificia de Salamanca, Spain

INTRODUCTION

Unsolicited commercial email also known as Spam is becoming a serious problem for Internet users and providers (Fawcett, 2003). Several researchers have applied machine learning techniques in order to improve the detection of spam messages. Naïve Bayes models are the most popular (Androutsopoulos, 2000) but other authors have applied Support Vector Machines (SVM) (Drucker, 1999), boosting and decision trees (Carreras, 2001) with remarkable results. SVM has revealed particularly attractive in this application because it is robust against noise and is able to handle a large number of features (Vapnik, 1998).

Errors in anti-spam email filtering are strongly asymmetric. Thus, false positive errors or valid messages that are blocked, are prohibitively expensive. Several authors have proposed new versions of the original SVM algorithm that help to reduce the false positive errors (Kolz, 2001, Valentini, 2004 & Kittler, 1998). In particular, it has been suggested that combining non-optimal classifiers can help to reduce particularly the variance of the predictor (Valentini, 2004 & Kittler, 1998) and consequently the misclassification errors. In order to achieve this goal, different versions of the classifier are usually built by sampling the patterns or the features (Breiman, 1996). However, in our application it is expected that the aggregation of strong classifiers will help to reduce more the false positive errors (Provost, 2001 & El-Hadi, 2005).

In this paper, we address the problem of reducing the false positive errors by combining classifiers based on multiple dissimilarities. To this aim, a diversity of classifiers is built considering dissimilarities that reflect different features of the data.

The dissimilarities are first embedded into an Euclidean space where a SVM is adjusted for each measure. Next, the classifiers are aggregated using a

voting strategy (Kittler, 1998). The method proposed has been applied to the Spam UCI machine learning database (Hastie, 2001) with remarkable results.

THE PROBLEM OF DISSIMILARITIES REVISITED

An important step in the design of a classifier is the choice of the proper dissimilarity that reflects the proximities among the objects. However, the choice of a good dissimilarity for the problem at hand is not an easy task. Each measure reflects different features of the dataset and no dissimilarity outperforms the others in a wide range of problems. In this section, we comment shortly the main differences among several dissimilarities that can be applied to model the proximities among emails. For a deeper description and definitions see for instance (Cox, 2001).

The Euclidean distance evaluates if the features that codify the spam differ significantly among the messages. This measure is sensible to the size of the emails. The cosine dissimilarity reflects the angle between the spam messages. The value is independent of the message length. It differs significantly from the Euclidean distance when the data is not normalized. The correlation measure checks if the features that codify the spam change in the same way in different emails. Correlation based measures tend to group together samples whose features are linearly related. The correlation differs significantly from the cosine if the mean of the vectors that represents the emails are not zero. This measure is distorted by outliers. The Spearman rank correlation avoids this problem by computing a correlation between the ranks of the features. Another kind of correlation measure that helps to overcome the problem of outliers is the Kendall- τ index which is related to the Mutual Information probabilistic measure.

When the emails are codified in high dimensional and noisy spaces, the dissimilarities mentioned above are affected by the 'curse of dimensionality' (Aggarwal, 2001 & Martín-Merino, 2004). Hence, most of the dissimilarities become almost constant and the differences among dissimilarities are lost (Hinneburg, 2000 & Martín-Merino, 2005). This problem can be avoided selecting a small number of features before the dissimilarities are computed.

COMBINING DISSIMILARITY BASED CLASSIFIERS

In this section, we explain how the SVM can be extended to work directly from a dissimilarity measure. Next, the ensemble of classifiers based on multiple dissimilarities is presented. Finally we comment briefly the related work.

The SVM is a powerful machine learning technique that is able to deal with high dimensional and noisy data (Vapnik, 1998). In spite of this, the original SVM algorithm is not able to work directly from a dissimilarity matrix. To overcome this problem, we follow the approach of (Pekalska, 2001). First, the dissimilarities are embedded into an Euclidean space such that the inter-pattern distances reflect approximately the original dissimilarity matrix. Next, the test points are embedded via a linear algebra operation and finally the SVM is trained and evaluated. We comment briefly the mathematical details.

Let $\mathbf{D} \in \mathbb{R}^{n \times n}$ be the dissimilarity matrix made up of the object proximities for the training set. A configuration in a low dimensional Euclidean space can be found via a metric multidimensional scaling algorithm (MDS) (Cox, 2001) such that the original dissimilarities are approximately preserved. Let $\mathbf{X} = [x_1, \dots, x_n]^T \in \mathbb{R}^{n \times p}$ be the matrix of the object coordinates for the training patterns. Define $\mathbf{B} = \mathbf{X} \mathbf{X}^T$ as the matrix of inner products which is related to the dissimilarity matrix via the following equation:

$$\mathbf{B} = -1/2 \mathbf{J} \mathbf{D}^{(2)} \mathbf{J} \quad (1)$$

where $\mathbf{J} = \mathbf{I} - 1/n \mathbf{1} \mathbf{1}^T \in \mathbb{R}^{n \times n}$ is the centering matrix, \mathbf{I} is the identity matrix and $\mathbf{D}^{(2)} = (\delta_{ij}^2)$ is the matrix of the square dissimilarities for the training patterns. If \mathbf{B} is positive semi-definite, the object coordinates in the low dimensional Euclidean space \mathbb{R}^k can be found through

a singular value decomposition (Golub, 1996):

$$\mathbf{X}_k = \mathbf{V}_k \mathbf{\Lambda}_k^{1/2}, \quad (2)$$

where $\mathbf{V}_k \in \mathbb{R}^{n \times k}$ is an orthogonal matrix with columns the first k eigen vectors of $\mathbf{X} \mathbf{X}^T$ and $\mathbf{\Lambda}_k = \text{diag}(\lambda_1 \dots \lambda_k) \in \mathbb{R}^{k \times k}$ is a diagonal matrix with λ_i the i -th eigenvalue. Several dissimilarities introduced in section 2 generate inner product matrices \mathbf{B} non semi-definite positive. Fortunately, the negative values are small in our application and therefore can be neglected without losing relevant information about the data (Pekalska, 2001).

Once the training patterns have been embedded into a low dimensional Euclidean space, the test pattern can be added to this space via a linear projection (Pekalska, 2001). Next we comment briefly the derivation.

Let $\mathbf{X}_k \in \mathbb{R}^{n \times k}$ be the object configuration for the training patterns in \mathbb{R}^k and $\mathbf{X}_n = [x_1, \dots, x_s]^T \in \mathbb{R}^{s \times k}$ the matrix of the object coordinates sought for the test patterns. Let $\mathbf{D}_n^{(2)} \in \mathbb{R}^{s \times n}$ be the matrix of the square dissimilarities between the s test patterns and the n training patterns that have been already projected. The matrix $\mathbf{B}_n \in \mathbb{R}^{s \times n}$ of inner products among the test and training patterns can be found as:

$$\mathbf{B}_n = -1/2 (\mathbf{D}_n^{(2)} \mathbf{J} - \mathbf{U} \mathbf{D}^{(2)} \mathbf{J}) \quad (3),$$

where $\mathbf{J} \in \mathbb{R}^{n \times n}$ is the centering matrix and $\mathbf{U} = 1/n \mathbf{1}^T \mathbf{1} \in \mathbb{R}^{s \times n}$. The derivation of equation is detailed in (Pekalska, 2001). Since the matrix of inner products verifies

$$\mathbf{B}_n = \mathbf{X}_n \mathbf{X}_k^T, \quad (4)$$

then, \mathbf{X}_n can be found as the least mean-square error solution to (4), that is:

$$\mathbf{X}_n = \mathbf{B}_n \mathbf{X}_k (\mathbf{X}_k^T \mathbf{X}_k)^{-1} \quad (5)$$

Given that $\mathbf{X}_k^T \mathbf{X}_k = \mathbf{\Lambda}_k$ and considering that $\mathbf{X}_k = \mathbf{V}_k \mathbf{\Lambda}_k^{1/2}$ the coordinates for the test points can be obtained as:

$$\mathbf{X}_n = \mathbf{B}_n \mathbf{V}_k \mathbf{\Lambda}_k^{-1/2}, \quad (6)$$

which can be easily evaluated through simple linear algebraic operations.

Figure 1. Aggregation of classifiers using a voting strategy. Bold patterns are misclassified by a single hyperplane but not by the combination.

The combination strategy proposed here is based on the evidence that different dissimilarities reflect different features of the dataset (see section 2). Therefore, classifiers based on different measures will misclassify a different set of patterns.

Figure 1 shows for instance that bold patterns are assigned to the wrong class by only one classifier but using a voting strategy the patterns will be assigned to the right class.

Hence, our combination algorithm proceeds as follows: First, the dissimilarities introduced in section 2 are computed. Each dissimilarity is embedded into an Euclidean space, training and test pattern coordinates are obtained using equations (2) and (6) respectively. To increase the diversity of classifiers, once the dissimilarities are embedded a bootstrap sample of the patterns is drawn. Next, we train a SVM for each dissimilarity and bootstrap sample. Thus, it is expected that misclassification errors will change from one classifier to another. So the combination of classifiers by a voting strategy will help to reduce the misclassification errors.

A related technique to combine classifiers is the Bagging (Breiman, 1996 & Bauer, 1999). This method generates a diversity of classifiers that are trained using several bootstrap samples. Next, the classifiers are aggregated using a voting strategy. Nevertheless there are three important differences between bagging and the method proposed in this section.

First, our method generates the diversity of classifiers by considering different dissimilarities and thus will induce a stronger diversity among classifiers. A second advantage of our method is that it is able to work directly with a dissimilarity matrix. Finally, the combination of several dissimilarities avoids the problem of choosing a particular dissimilarity for the application we are dealing with. This is a difficult and time consuming task.

Notice that the algorithm proposed earlier can be easily applied to other classifiers such as the k-nearest neighbor algorithm that are based on distances.

EXPERIMENTAL RESULTS

In this section, the ensemble of classifiers proposed is applied to the identification of spam messages.

The spam collection considered is available from the UCI Machine learning database (Hastie, 2001). The corpus is made up of 4601 emails from which 39.4 % are spam and 60.6 % legitimate messages. The number of features considered to codify the emails is 57 and they are described in (Hastie, 2001).

Figure 2. Eigenvalues for the multidimensional scaling algorithm with the cosine dissimilarity

The dissimilarities have been computed without normalizing the variables because this may increase the correlation among them. Once the dissimilarities have been embedded in a Euclidean space, the variables are normalized to unit variance and zero mean. This preprocessing improves the SVM accuracy and the speed of convergence.

Regarding the ensemble of classifiers, an important issue is the dimensionality in which the dissimilarity matrix is embedded. To this aim, a metric Multidimensional Scaling algorithm is first run. The number of eigenvectors considered is determined by the curve induced by the eigenvalues. For the dataset considered,

figure 2 shows that the first twenty eigenvalues preserve the main structure of the dataset.

The combination strategy proposed in this paper has been also applied to the k-nearest neighbor classifier. An important parameter in this algorithm is the number of neighbors which has been estimated using 20 % of the patterns as a validation set.

The classifiers have been evaluated from two different points of view: on the one hand we have computed the misclassification errors. But in our application, false positives errors are very expensive and should be avoided. Therefore false positive errors are also computed.

Table 1. Experimental results for the ensemble of SVM classifiers. Classifiers based solely on a single dissimilarity and Bagging have been taken as reference

| Method | Linear Kernel | | Polynomial Kernel | |
|--------------------|---------------|----------------|-------------------|----------------|
| | Error | False positive | Error | False positive |
| Euclidean | 8.1% | 4.0% | 15% | 11% |
| Cosine | 19.1% | 15.3% | 30.4% | 8% |
| Correlation | 18.7% | 9.8% | 31% | 7.8% |
| Manhattan | 12.6% | 6.3% | 19.2% | 7.1% |
| Kendall- τ | 6.5% | 3.1% | 11.1% | 5.4% |
| Spearman | 6.6% | 3.1% | 11.1% | 5.4% |
| Bagging Euclidean | 7.3% | 3.0% | 14.3% | 4% |
| Combination | 6.1% | 3% | 11.1% | 1.8% |

Parameters: Linear kernel: $C=0.1$, $m=20$; Polynomial kernel: Degree=2, $C=5$, $m=20$

Table 2. Experimental results for the ensemble of k-NN classifiers. Classifiers based solely on a single dissimilarity and Bagging have been taken as reference

| Method | Error | False positive |
|--------------------|--------------|----------------|
| Euclidean | 22.5% | 9.3% |
| Cosine | 23.3% | 14.0% |
| Correlation | 23.2% | 14.0% |
| Manhattan | 23.2% | 12.2% |
| Kendall- τ | 21.7% | 6% |
| Bagging | 19.1% | 11.6% |
| Combination | 11.5% | 5.5% |

Parameters: $k=2$

Finally the errors have been evaluated considering a subset of 20 % of the patterns drawn randomly without replacement from the original dataset.

Table 1 shows the experimental results for the ensemble of classifiers using the SVM. The method proposed has been compared with bagging introduced in section 3 and with classifiers based on a single dissimilarity.

From the analysis of table 1 the following conclusions can be drawn:

- The combination strategy improves significantly the Euclidean distance which is usually considered by most SVM algorithms.
- The combination strategy with polynomial kernel reduces significantly the false positive errors of the best single classifier. The improvement is smaller for the linear kernel. This can be explained because the non-linear kernel allow us to build classifiers with larger variance and therefore the combination strategy can achieve a larger improvement of the false positive errors. We also report that for the combination strategy as the C parameter increases the false positive errors converge to 0 although the false negative errors increase.
- The combination strategy proposed outperforms a widely used aggregation method such as Bagging. The improvement is particularly important for the polynomial kernel.

Table 2 shows the experimental results for the ensemble of k-NNs classifiers. As in the previous case, the combination strategy proposed improves particularly the false positive errors of classifiers based on a single distance. We also report that Bagging is not able to reduce the false positive errors of the Euclidean distance. Besides, our combination strategy improves significantly the Bagging algorithm. Finally, we observe that the misclassification errors are larger for k-NN than for the SVM. This can be explained because the SVM has a higher generalization ability.

CONCLUSIONS AND FUTURE RESEARCH TRENDS

In this paper, we have proposed an ensemble of classifiers based on a diversity of dissimilarities. Our approach aims to reduce particularly the false positive

errors of classifiers based solely on a single distance. Besides, the algorithm is able to work directly from a dissimilarity matrix. The algorithm has been applied to the identification of spam messages.

The experimental results suggest that the method proposed help to improve both, misclassification errors and false positive errors. We also report that our algorithm outperforms classifiers based on a single dissimilarity and other combination strategies such as bagging.

As future research trends, we will try to apply other combination strategies that assign different weight to each classifier.

SVD: Singular Value Decomposition. Linear algebra operation that is used by many optimization algorithms.

SVM: Support Vector Machines classifier.

UCE: Unsolicited Commercial Email, also known as Spam.

Evolutionary Algorithms in Discredibility Detection

Bohumil Sulc

Czech Technical University in Prague, Czech Republic

David Klimanek

Czech Technical University in Prague, Czech Republic

INTRODUCTION

Evolutionary algorithms are well known optimization techniques suitable for solving various kinds of problems (Ruano, 2005). The new application of evolutionary algorithms represents their use in the detection of biased control loop functions caused by controlled variable sensor discredibility (Klimanek, Sulc, 2005). *Sensor discredibility* occurs when a sensor transmitting values of the controlled variable provides inexact information, however the information is not absolutely faulty yet. Use of discreditable sensors in control circuits may cause the real values of controlled variables to exceed the range of tolerated differences, whereas zero control error is being displayed. However, this is not the only negative consequence. Sometimes, sensor discredibility is accompanied with undesirable and hardly recognizable side effects. Most typical is an increase of harmful emission production in the case of combustion control (Sulc, Klimanek, 2005).

We have found that evolutionary algorithms are useful tools for solving the particular problem of finding a software-based way (co-called software redundancy) of sensor discredibility detection. Software redundancy is a more economic way than the usual hardware redundancy, which is otherwise necessary in control loop protection against this small, invisible control error occurrence.

Namely, the standard genetic algorithm and the simulated annealing algorithm have been successfully applied and tested to minimize the given cost function; by means of these algorithms newly developed method is able to detect controlled variable sensor discredibility. When applied to combustion processes, production of harmful emissions can be kept within accepted limits.

Used application of evolutionary algorithms inclusive terminology transfer reflecting this application area

can serve as an explanatory case study helping readers in better understanding the way how the evolutionary algorithms operate.

BACKGROUND

The above-mentioned controlled variable sensor discredibility detection represents a specific part of the fault detection field in control engineering. According to some authors (Venkatasubramanian, Rengaswamy, 2003, Korbic, 2004), fault detection methods are classified into three general categories: quantitative model-based methods, qualitative model-based methods, and process history based methods. In contrast to the mentioned approaches, where priori knowledge about the process is needed, for the controlled variable sensor discredibility detection it is useful to employ methods of evolutionary algorithms. The main advantage of such a solution is that necessary information about the changes in controlled variable sensor properties can be obtained with the help of evolutionary algorithms based on the standard process data – this is, in any case, acquired and recorded for the sake of process control.

In order to apply evolutionary algorithms to controlled variable sensor discredibility detection, a cost function was designed as a *residual function* e defined by the absolute value of difference between the sensor model output (y_m) and the real sensor output (y_{real}),

$$e = |y_{real} - y_m| \quad (1)$$

The design of residual function e has been explained in detail (e.g. in Sulc, Klimanek, 2005).

In most sensor models it is assumed that the sensor output is proportional only to one input (Koushanfar, 2003), so that the sensor model equation is

$$y_m = k_m x_{est} + q_m, \quad (2)$$

where parameter k_m represents the gain of the sensor model, parameter q_m expresses the shift factor, and x_{est} is the estimated sensor model input, which represents the physical (real) value of the control variable. The physical value of the control variable is not available for us because we expect that the sensor is not reliable and we want to detect this stage. However, we can estimate this value from the other process data that are acquired usually for the purposes of the information system. This estimation is usually based on steady-state data, so that it is important to detect the steady state of the process.

Basically, the underlying idea of applying the evolutionary algorithm is then based on finding a vector of the sensor model parameter for which the value of residual function e is minimal.

Advantages of the Evolutionary Algorithm Applied to Discredibility Detection

In principle, any optimization method could be used for the mentioned optimization task. The problem is that the sensor model input is an unknown, dynamically-changing variable. Therefore, the choice and the parameter selection must include certain element of a random selection from many alternatives, which is fulfilled in the case of evolutionary algorithms. The higher computational time requirements do not matter in the case of sensor discredibility detection, because the loss of credibility is the result of a gradual development.

Problem Statement

A particular task of evolutionary algorithms in the solved problem is e.g. a finding extreme of a given cost function. We have utilized the evolutionary algorithms to minimize the given cost function (in fault detection terminology a residual function). Based on this minimization, it is possible to detect that the control variable sensor is providing biased data.

THE STANDARD GENETIC ALGORITHM AND THE SIMULATED ANNEALING ALGORITHM IN DISCREDIBILITY DETECTION

Both methods have been tested and proved to be legitimate for use. Unlike general genetic presentations of the methods, we will present the methods in a transformed way, based on the use of terms from the field of fault detection. From the engineering view point this should facilitate understanding of both procedures (Klimanek, Sulc, 2005). In our text, the terms introduced in the theory of evolutionary algorithms are indicated by the abbreviation "ET".

The Standard Genetic Algorithm

In controlled variable sensor discredibility detection that uses genetic algorithm methods, the following steps are required (procedure by Fleming & Purshouse, 1995) (Figure 1):

1. Initialization – during initialization, the evolutionary time is set to zero and an initial set of vectors containing the sensor model parameters (called population in ET) is randomly generated within an expected range of reasonable values for each of the parameters. For each of the parameter vectors of the sensor model (in ET, individuals of the population), the value of the residual function

Figure 1 A flow chart of the standard genetic algorithm applied for discredibility detection

- (1) is evaluated. Also, the average value of the residual function values is computed.
2. New set of parameter vectors – after starting the iteration process, a new set of parameter vectors is generated (in ET, new population) when the selection operator is employed. Selecting a set of the new parameter vectors, the following algorithm is used: the parameter vector of the sensor model that provides residual values lower than the average value is replicated into the next subset for generating new parameter candidates in more copies than in the original set, and the individuals with below-average residual values are rejected (Witczak, Obuchowicz, Korbicz, 2002).
3. Crossover and mutation (ET) – next comes the crossover operation over the randomly selected pairs of the parameter vector of the sensor model of the topical set. In the presenting application of the standard genetic algorithm, the selected sensor model parameters are coded into binary strings and the standard one point crossover operator is used. The mutation operator mimics random mutations (Fleming, Purshouse, 1995). The newly created parameters are coded into binary strings and one bit of each string is switched with random probability. The value of the residual function (1) for the current run is evaluated. Also, the average value of the residual function values is computed.
4. Stopping-criterion decision – if the stopping criterion is not met, a return to step 2 repeats the process. The stopping criterion is met, e.g. when the size of the difference between the average of the residual values from the current run and the average of the residual values from the previous run is lower then the given size (Fleming, Purshouse, 2002).

Simulated Annealing Algorithm

Controlled variable sensor discredibility detection via simulated annealing can be described by the following steps (Figure 2):

5. Initialization – an initial control parameter is set (in ET, initial annealing temperature). The control parameter is used to evaluate the Boltzmann criterion (King, 1999), which affects the acceptance of the current parameter vector of the sensor model

in step 3. A vector of random values of the sensor model parameters is selected and the value of the residual function is computed.

6. New set of parameter vectors – the iteration index is increased and, using a stochastic strategy, a new vector of the sensor model parameters is randomly generated (in ET it is spoken about generating new individuals) and the corresponding value of the residual variable is obtained (in ET, value of the cost function).
7. Boltzmann criterion computation – the difference between the residual value obtained in step 2 and the residual value from the previous iteration is evaluated. If the difference is negative, then the new parameter vector is accepted automatically. Otherwise, the algorithm may accept the new parameter vector based on the Boltzmann criterion. The control parameter is weighted with a coefficient λ (in ET, gradual temperature reduction). If the control parameter is less than or equal to the given final control parameter, then the stop criterion is met and the current vector of the sensor model parameters is accepted. Otherwise, returning to step 3 repeats the process of optimizing search.

Comparison of Usability of the Algorithms for Discredibility Detection

The comparison of both evolutionary algorithms applied to controlled variable sensor discredibility detection

Figure 2. A flow chart of the simulated annealing algorithm applied for dis-credibility detection

is shown by Figure 5. This comparison represents a part of results from paper Sulc, Klimanek. (2006). It is evident, that the simulated annealing algorithm needs more evaluation time for one evaluation period – a period for simulated annealing required 80 iterations, while genetic algorithm needed 40 iterations. This difference is because genetic algorithm works with a group of potential solutions, while simulated annealing compares only two potential solutions and accepts better one.

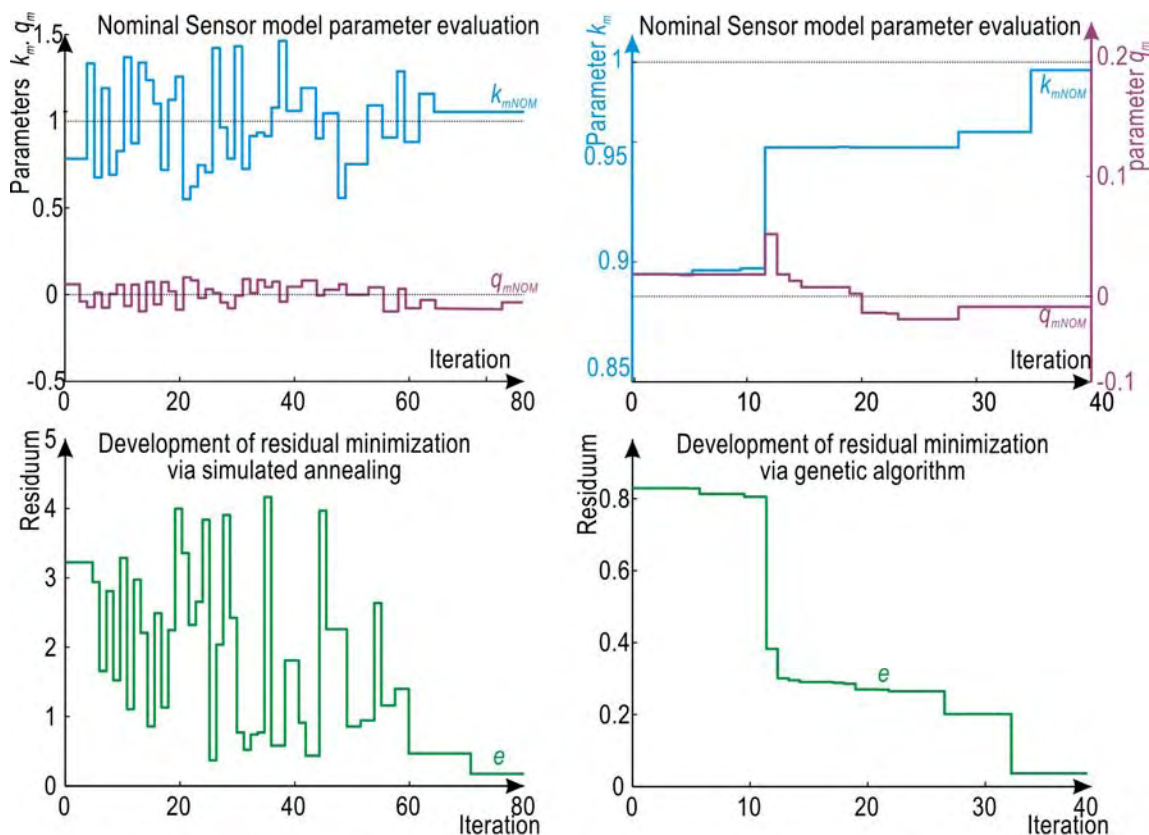

No difference was found between the two evolutionary algorithms used here; their good convergence depends mainly on the algorithm settings. Although evolutionary algorithms are generally much more time consuming than other optimizing procedures, this consideration does not matter in control variable sensor discredibility detection. This is because control variable

sensor discredibility has no conclusive impacts on the control results and the time needed for the detection does not affect the control process.

Testing Model-Based Sensor Discredibility Detection Method

The model-based control variable sensor discredibility detection method using evolutionary algorithms was tested to find whether the method is able to detect the control variable sensor properties changes via presented evolutionary algorithms. The simulation experiments are more described in (Klimanek, Sulc 2006a, Klimanek, Sulc 2006b). Results from the simulated experiments were summarized and they can be graphically demonstrated in the next paragraph.

Figure 3. Detection of gradual changes of the level sensor gain via genetic algorithm and the simulated annealing algorithm

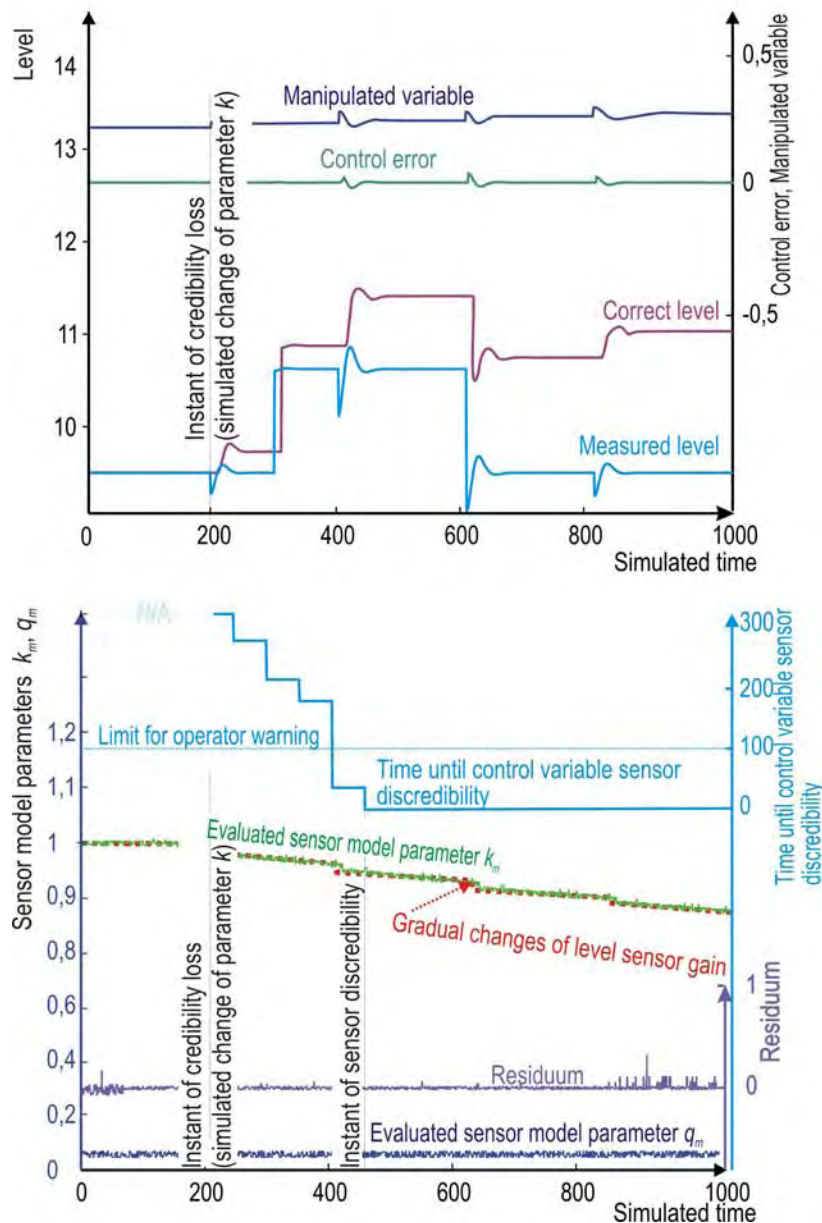

Results and Findings from the Tests

Figure 4 depicts a simulation run during which the sensor gain has been gradually decreased from a starting (correct) value. It can be seen that after the sensor properties has been changed, the measured value of

the controlled variable (in this case the water level) is different from the correct value.

It is apparent that the algorithm used for sensor model parameter detection (in this case the genetic algorithm) is able to find the sensor model gain k_m , because the sensor model parameter development corresponds to the simulated real sensor parameter changing.

Figure 4. Detection of gradual changes of the level sensor gain via genetic algorithm

The sensor level discredibility detection results obtained using the simulated annealing algorithm, were similar. Figure 5 shows results obtained when the model-based method using the simulated annealing algorithm was tested. A step change of sensor gain was simulated and it is obvious that the algorithm was able to capture the change.

By this method the operator is informed about the estimated time remaining before sensor discredibility occurs. If the time is critical, the operator also receives timely a warning about the situation.

Figure 5. Detection of the step change of the level sensor gain via simulated annealing method

FUTURE TRENDS

It can be expected in future that tools for the controlled variable discredibility detection will be a standard accessory of any standard PID controller. On the present from economic reasons, the cases, when the described method using evolutionary algorithms is mostly justified to be implemented, are linked to revelation of undesirable side effects (increased production of harmful emissions CO , NO_x , or, in the case of bioenergetic processes, increase of unwanted production of CO_2). Except use for a standard detection of the changes in the controlled variable sensor, the discredibility detection provides possibilities to warn operator against occurrence of the control loop inaccuracy, or even to forecast it.

CONCLUSION

Implementation feasibility of the evolutionary algorithms in a model-based controlled variable sensor discredibility has been demonstrated here. In two variations of the standard evolutionary algorithms - the genetic algorithm and the simulated annealing algorithm, designed procedure of sensor discredibility detection was presented.

In both cases, the time needed for the evaluation was several minutes. In the case of the application for discredibility detection, this time demand does not matter because such small malfunctions do not lead to fatal errors in control loop operation and discredibility is usually a long developing process.

Evolutionary algorithms have become a useful tool in discovering hidden inaccuracy in the control loops. Discredibility detection saves costs on redundant controlled variable sensors, which are required if the controlled variable sensor discredibility is detected via hardware redundancy on the assumption that the costs for additional sensors are not negligible, of course.

The importance of discredibility detection using evolutionary algorithms can be found, e.g. in biomass combustion processes (due to the penalties for overstepped limits in harmful emissions), and also in the food-processing industry, where side effects may not be harmful, but rather unpleasant (i.e. bad odors).

KEY TERMS

The following terms and definitions introduce a fault detection engineering interpretation of the terms usual in the evolutionary algorithm vocabulary. This should facilitate orientation in the presented engineering problem.

Chromosome: A particular sensor model parameter vector (a term for individuals used in evolutionary terminology).

Cost Function: A criterion evaluating level of the congruence between the sensor model output and the

real sensor output. In the fault detection terminology, the cost function corresponds to the term residuum (or residual function).

Evolutionary Time: The number assigned to steps in the sequence of iteration performed during a search for sensor model parameters based on evolutionary development.

Individual: A vector of the sensor model parameters in a set of possible values (see population).

Initial Annealing Temperature: An initial algorithm parameter. Annealing temperature is used as a measure of evolutionary progress during the simulated annealing algorithm run.

Population: A set of the vectors of the sensor model parameters with which the sensor model has a chance to approach the minimum of the residual function.

Population Size: The number of the sensor model parameter vectors taken into the consideration in population.

Sensor Discredibility: A stage of the controlled variable sensor at which the sensor is not completely out of function yet, but its properties have gradually changed to the extent that the data provided by the sensor are so biased that the tolerated inaccuracy of the controlled variable is over-ranged and usually linked with possible side effects.

Evolutionary Approaches for ANNs Design

Antonia Azzini

University of Milan, Italy

Andrea G. B. Tettamanzi

University of Milan, Italy

INTRODUCTION

Artificial neural networks (ANNs) are computational models, loosely inspired by biological neural networks, consisting of interconnected groups of artificial neurons which process information using a connectionist approach.

ANNs are widely applied to problems like pattern recognition, classification, and time series analysis. The success of an ANN application usually requires a high number of experiments. Moreover, several parameters of an ANN can affect the accuracy of solutions. A particular type of evolving system, namely neuro-genetic systems, have become a very important research topic in ANN design. They make up the so-called Evolutionary Artificial Neural Networks (EANNs), i.e., biologically-inspired computational models that use evolutionary algorithms (EAs) in conjunction with ANNs.

Evolutionary algorithms and state-of-the-art design of EANN were introduced first in the milestone survey by Xin Yao (1999), and, more recently, by Abraham (2004), by Cantu-Paz and Kamath (2005), and then by Castellani (2006).

The aim of this article is to present the main evolutionary techniques used to optimize the ANN design, providing a description of the topics related to neural network design and corresponding issues, and then, some of the most recent developments of EANNs found in the literature. Finally a brief summary is given, with a few concluding remarks.

ARTIFICIAL NEURAL NETWORK DESIGN

In ANN design, the successful application of an ANN usually demands much experimentation. There are many parameters to set. Some of them involve ANN type, others the number of layers and nodes defining

the architecture and the connection weights. Also the training data are an important factor, and a great deal of attention must be paid to the test data to make sure that the network will generalize correctly on data which has not been trained on.

Feature selection, structure design, and weight training can be regarded as three search problems in the discrete space of subsets of data attributes, the discrete space of the possible ANN configurations, and the continuous space of the ANN parameters, respectively.

Architecture design is crucial in the successful application of ANNs because it has a significant impact on their information-processing capabilities. Indeed, given a learning task, an ANN with only a few connections and linear nodes may not be able to perform the task at all, while an ANN with a large number of connections and nonlinear nodes may overfit noise in the training data and lack generalization. The main problem is that there is no systematic way to design an optimal architecture for a given task automatically.

Several methods have been proposed to overcome these shortcomings. This chapter focuses on one of them, namely EANNs. One distinct feature of EANNs is their adaptability to a dynamic environment. EANNs can be regarded as a general framework for adaptive systems, i.e., systems that can change their architectures and learning rules appropriately without human intervention.

In order to improve the performance of EAs, different selection schemes and genetic operators have been proposed in the literature. This kind of evolutionary learning for ANNs has also been introduced to reduce and, if possible, to avoid the problems of traditional gradient descent techniques, such as Backpropagation (BP), that lie in the trapping in local minima. EAs are known to be little sensitive to initial training conditions, due to their being global optimization methods, while a gradient descent algorithm can only find a local

optimum in a neighbourhood of the initial solution. EANNs provide a solution to these problems and an alternative for controlling network complexity.

ANN design can be regarded as an optimization problem. Tettamanzi and Tomassini (2001) presented a discussion about evolutionary systems and their interaction with neural and fuzzy systems, and Cantu-Paz and Kamath (2005) also described an empirical comparison of EAs and ANNs for classification problems.

EVOLUTIONARY ARTIFICIAL NEURAL NETWORKS

There are several approaches to evolve ANNs, that usually fall into two broad categories: *problem-independent* and *problem-dependent* representation of EAs. The former are based on a general representation, independent of the type and structure of the ANN sought for, and require the definition of an encoding scheme suitable for Genetic Algorithms (GAs). They can include mapping between ANNs and binary representation, taking care of decoders or repair algorithms, but this task is not usually easy.

The latter are EAs where chromosome representation is a specific data structure that naturally maps to an ANN, to which appropriate genetic operators apply.

EAs are used to perform various tasks, such as connection weight training, architecture design, learning rule adaptation, input feature selection, connection weight initialization, rule extraction from ANNs, etc. Three of them are considered as the most popular at the following levels:

- *Connection weights* concentrates just on weights optimization, assuming that the architecture of the network is given. The evolution of weights introduces an adaptive and global approach to training, especially in the reinforcement learning and recurrent network learning paradigm, where gradient-based training algorithms often experience great difficulties.
- *Learning rules* can be regarded as a process of “learning how to learn” in ANNs where the adaptation of learning rules is achieved through evolution. It can also be regarded as an adaptive process of automatic discovery of novel learning rules.

- *Architecture* enables ANNs to adapt their topologies to different tasks without human intervention. It also provides an approach to automatic ANN design as both weights and structures can be evolved. In this case a further subdivision can be made by defining a “pure” architecture evolution and a simultaneous evolution of both architecture and weights.

Other approaches consider the evolution of transfer functions of an ANN and input feature selection, but they are usually applied in conjunction with one of the three methods above in order to obtain better results.

The use of evolutionary learning for ANNs design is no more than two decades old. However, substantial work has been made in these years, whose main outcomes are presented below.

Weight Optimization

Evolution of weights may be regarded as an alternative training algorithm. The primary motivation for using evolutionary techniques instead of traditional gradient-descent techniques such as BP, as reported by Rumelhart et al. (1986), lies in avoiding trapping in local minima and the requirement that the activation function be differentiable. For this reason, rather than adapting weights based on local improvement only, EAs evolve weights based on the fitness of the whole network.

Some approaches use GAs with real encodings for biases and weights, like in the work presented by Montana and Davis (1989); others used binary weights encoding at first, and then implemented a modified version with real encodings as Whitley *et al.* (1990). Mordaunt and Zalzala (2002) implemented a real number representation to evolve weights, analyzing evolution with mutation and a multi-point crossover, while Seiffert (2001) described an approach to completely substitute a traditional gradient descent algorithm by a GA in the training phase.

Often, during the application of GAs, some problems, e.g., premature convergence and stagnation of solution can occur as reported by Goldberg (1992). In order to solve this problem, an improved algorithm was proposed by Yang et al. (2002), where a genetic algorithm, based on evolutionary stable strategy, was implemented to keep the balance between population diversity and convergence speed during evolution.

Recently, a new GA was proposed by Pai (2004), where a genetic inheritance operator was implemented to determine the weights of EANN, without considering mutation operators, but only two-point crossover for reproduction, applying it to decimal chromosomes.

Learning Rule Optimization

In supervised learning algorithms, standard BP is the most popular method for training multilayer networks. The design of training algorithms, in particular the learning rules used to adjust connection weights, depends on the type of ANN architecture considered. Several standard learning rules have been proposed, but designing an optimal learning rule becomes very difficult when there is little prior knowledge about the network topology, producing a very complex relationship between evolution and learning. The evolutionary approach becomes important in modelling the creative process since newly evolved learning rules can deal with a complex and dynamic environment.

The first kind of optimization considers the adjustment of learning parameters and can be seen as the first attempt to evolve learning rules. They comprise BP parameters, like the learning rate and momentum, and genetic parameters, like mutation and crossover probabilities. Some works have been carried out by Merelo et al. (2002), that presented several solutions for the optimal learning parameters of multilayer competitive-learning neural networks.

Considering learning-rule optimization, one of the first studies was conducted by Chalmers (1990). He also noticed that discovering complex learning rules using GAs is not easy, due to the highly complex genetic coding used, making the search space large and hard to explore, while GAs used a simpler coding which allows known learning rules as a possibility, making the search very biased. In order to overcome these limitations, Chalmers suggested to apply GP, a particular kind of GA. Several studies have been carried out in this direction and some of them are described, along with a new approach presented by Poli and Radi (2002).

Architecture Optimization

The design of an optimal architecture can be formulated as a search problem in the architecture space, where each point represents an ANN topology. As pointed out by Yao (1999), given some performance (optimality)

criteria, e.g., minimum error, learning speed, lower complexity, etc., about architectures, the performance level of all these forms a surface in the design space. Several approaches have been carried out in this direction. A neuro-evolutionary approach was presented by Miikkulainen and Stanley (2002), using augmenting topologies. It has been designed specifically to outperform the solutions that employ a principled method of crossover of different topologies, to protect structural innovation using speciation, and to incrementally grow from minimal structure.

Another work carried out by Wang et al. (2002), considered the definition of an optimal network that was based on the combination of constructing and pruning by GAs, while, more recently, Bevilacqua et al. (2006) presented a multi-objective GA approach to optimize the search for the optimal topology, based on *Schema Theory*.

One of the most important forms of deception in ANNs structure optimization arises from the many-to-one and from one-to-many mapping from genotypes in the representation space to phenotypes in the evaluation space. The existence of networks functionally equivalent and with different encodings makes evolution inefficient. This problem is termed as the *competing convention problem*. Other important issues involve representation and the definition of the EA. In the encoding phase, an important aspect is to decide how much information about architecture should be encoded into the genotype. Then, the performance of ANNs strongly depends on their topology, considering size and structure, and, consequently, its definition characterizes networks features like its learning process speed, learning precision, noise tolerance, and generalization capability.

Transfer Function Optimization

Transfer function perturbations can begin with a fixed function, as linear, sigmoidal or gaussian, and allow the GA to adapt to a useful combination according to the situation. Some work has been carried out by Yao and Liu (1996) in order to apply a transfer function adaptation over generations, and by Figueira and Poli (1999), with a GP algorithm evolving functions.

To improve solutions, often, this kind of evolution is carried out together with the other kinds of ANNs optimizations, here described.

Input Data Selection

One of the most important factors for training neural networks is the availability and the integrity of data. They should represent all possible states of the problem considered, and they should have enough patterns for building also the test and validation set.

The consistency of all data has to be guaranteed, and the training data must be representative of the problem, in order to avoid overfitting.

Input data selection can be regarded as a search problem in the discrete space of the subsets of data attributes. The solution requires the removal of unnecessary, conflicting, overlapping and redundant features in order to maximize the classifier accuracy, compactness, and learning capabilities.

Input data reduction has been approached by Reeves and Taylor (1998), who applied genetic algorithms to select training sets for a kind of ANNs, and by Castellani (2006), embedding the search for the optimal feature set into the training phase.

Joint Evolution of Architecture and Weights

The drawbacks related to individual architecture and weights evolutionary techniques can be overcome with approaches that consider their conjunction.

The advantage of combining these two basic elements of an ANN is that a completely functioning network can be evolved without any intervention by an expert.

Several methods that evolve both the network structure and the connection weights were proposed in the literature.

Castillo et al. (1999) presented a method to search for the optimal set of weights, the optimal topology and learning parameters using a GA for the network evolution and BP for network training, while Yao et al. (1997, 2003) implemented, respectively, an evolutionary system for evolving feedforward ANNs based on evolutionary programming, and, more recently, a novel constructive algorithm for training cooperative NN ensembles. Azzini and Tettamanzi (2006) presented a neuro-genetic approach for the joint optimization of network structures and weights, taking advantage of BP as a specialized decoder, and Pedrajas et al. (2003) proposed a cooperative co-evolutionary method for ANN design.

OPEN ISSUES

There are still several open issues in EANNs research.

Regarding connection weights, a critical aspect is that the structure has to be predetermined, giving some problems when such a topology is difficult to define in the first place.

Also in learning rule evolution, the design of training algorithms, in particular the learning rules, depends on the type of the network architecture. Therefore, the design of such rules can become very difficult when there is little prior knowledge about the network topology, giving a complex relationship between evolution and learning.

The architecture evolution has an important impact on the neural network evolution, and the evolution of pure architecture presents difficulties in evaluating fitness accurately.

The simultaneous evolution of architecture and weights is one of the most interesting evolutionary ANNs techniques, and nowadays it concerns useful solutions for ANN design. Different works are carried out in these directions and are still open issues. Some of them concern about the application of cooperative or competitive co-evolutionary approaches, some others regarding the design of NN ensembles.

CONCLUSION

This work presents a survey of the state of the art of evolutionary systems investigated in these decades and presented in the literature. In particular, this work focuses on the application of evolutionary algorithms to neural network design optimization.

Several approaches for NN evolution are presented, together with some related works, and for each method the most important features are presented together with their main advantages and shortcomings.

KEY TERMS

Adaptive System: System able to adapt its behavior according to changes in its environment or in parts of the system itself.

Artificial Neural Networks: Models inspired by the working of the brain, considered as a combination of neurons and synaptic connections, which are capable of transmitting data through multiple layers, giving a system able to solve different problems like pattern recognition and classification.

Backpropagation Algorithm: A supervised learning technique used for training ANNs. It is based on a set of recursive formulas for computing the gradient vector of the error function, that can be used in a first-order method like gradient descent.

Error Backpropagation: Essentially a search procedure that attempts to minimize a whole network error function such as the sum of the squared error of the network output over a set of training input/output pairs.

Evolutionary Algorithms: Algorithms based on models that consider ‘artificial’ or ‘simulated’ genetic evolution of individuals in a defined environment. They are a broad class of stochastic optimization algorithms, inspired by biology and in particular by those biological processes that allow populations of organisms to adapt to their surrounding environment: genetic inheritance and survival of the fittest.

Evolutionary Artificial Neural Networks: Special class of artificial neural networks in which evolution is another fundamental form of adaptation in addition to learning. They are represented by biologically inspired computational models that use evolutionary algorithms in conjunction with neural networks to solve problems.

Evolutionary Computation: In computer science it is a subfield of artificial intelligence (more particularly computational intelligence) involving combinatorial optimization problems. Evolutionary computation defines the quite young field of the study of computational systems based on the idea of natural evolution and adaptation.

Multi-Layer Perceptrons (MLPs): Class of neural networks that consists of a feed-forward fully connected network with an input layer of neurons, one or more hidden layers and an output layer. The output value is obtained through the sequence of activation functions defined in each hidden layer. Usually, in this kind of network, the supervised learning process is the back-propagation algorithm.

Search Space: Set of all possible situations of the problem that we want to solve could ever be in.

Evolutionary Approaches to Variable Selection

Marcos Gestal

University of A Coruña, Spain

José Manuel Andrade

University of A Coruña, Spain

INTRODUCTION

The importance of juice beverages in daily food habits makes juice authentication an important issue, for example, to avoid fraudulent practices.

A successful classification model should address two important cornerstones of the quality control of juice-based beverages: to monitor the amount of juice and to monitor the amount (and nature) of other substances added to the beverages. Particularly, sugar addition is a common and simple adulteration, though difficult to characterize. Other adulteration methods, either alone or combined, include addition of water, pulp wash, cheaper juices, colorants, and other undeclared additives (intended to mimic the compositional profiles of pure juices) (Saavedra, García, & Barbas, 2000).

VARIABLE SELECTION BY MEANS OF EVOLUTIONARY TECHNIQUES

This chapter presents several approaches to address the variable selection problem. All of them are based on evolutionary techniques. They can be divided into two groups. First group of techniques are based on different codifications of a traditional Genetic Algorithm (GA) population and different specifications for the evaluation function. Second group shows a modification in the traditional Genetic Algorithm to improve the generalization capability by adding a new population and an approach based on the evolution of subspecies into the genetic population.

BACKGROUND

A range of analytical techniques have been used to deal with authentication problems. These include high performance liquid chromatography (Yuan & Chen,

1999), gas chromatography (Stöber, Martin & Pèp-
pard, 1998) and isotopic methods (Jamin, González,
Remaud, Naulet & Martin, 1997). Unfortunately, they
are expensive and slow.

Infrared Spectrometry (IR) (Rodríguez-Saona, Fry,
McLaughlin, & Calvey, 2001) is a fast and convenient
technique to perform screening studies in order to assess
the quantity of pure juice in commercial beverages.
The interest lies in developing, from the spectroscopy
data, classification methods that might enable the de-
termination of the amount of natural juice contained
in a sample.

However, the information gathered from the IR
analyses has some fuzzy characteristics (random
noise, unclear chemical assignment, etc.), so analytical
chemists tend to use techniques like Artificial Neural
Networks (ANN) (Haykin, 1999) or develop ad-hoc
classification models. Previous studies (Gestal, Gómez-
Carracedo, Andrade, Dorado, Fernández, Prada, &
Pazos, 2005) showed that ANN classified apple juice
beverages according to the concentration of natural
juice they contained and that ANN had advantages over
classical statistical methods, such as robust models and
easy application of the methodology on R&D labora-
tories. Disappointingly, the large number of variables
derived from IR spectrometry makes ANNs time-con-
suming during training and, most important, makes it
very difficult to establish relationships between these
variables and the analytical knowledge.

Several approaches were used to reduce the number
of variables to a small subset, which should retain the
classification capabilities of the overall dataset. Hence,
the ANN training process and the interpretation of the
results would be highly improved.

Furthermore, previous variable selection would
yield other advantages: cost reduction (if the classifi-
cation model requires a reduced set of data, the time
needed to obtain them will be shorter; increased effi-
ciency (if the system processes less information, less

time for processing it will be required); understanding improvement (if two models resolve the same task, but one of them uses less information this would be more thoroughly interpreted. Therefore, the simpler the model, the easier the knowledge extraction and the easier the understanding, the easier the validation).

In addition, it was proved the analysis of IR data involved a highly multimodal problem, as many combinations of variables each (obtained using a different method) led to similar results when the samples were classified.

GENETIC ALGORITHMS

A GA (Holland, 1975)(Goldberg, 1989) is a recurrent and stochastic process that operates with a group of potential solutions to a problem, known as genetic population, based on one of the Darwin's principles: the survival of the best individuals (Darwin, 1859).

Briefly a GA works as follows. Initially, a population of solutions is generated randomly and the solutions evolve continuously after consecutive stages of cross-overs and mutations. Every individual at the population has an associated value that quantifies associated its usefulness (adjustment or fitness), in accordance to its adequacy to solve the problem. This value has to be obtained for each potential solution and constitutes the quantitative information the evolutionary algorithm will use to guide the search. The process will continue until a predetermined stopping criterion is reached. This might be a particular threshold error for the solution or a certain number of generations (populations).

Therefore, different basic steps will be required to implement a GA: codification of the problem, which results in a population structure, initialisation of the first population, defining a fitness function to evaluate how good is each individual to solve the problem and, finally, a cyclic procedure of reproductions and replacements (Michalewicz, 1999; Goldberg, 2002).

DATA DESCRIPTION

In the present practical application, the spectral range measured by IR spectrometry (wavenumbers from 1250 cm⁻¹ to 900 cm⁻¹) provided 176 absorbances (which measured light absorption)(Gómez-Carracedo, Gestal, Dorado & Andrade, 2007).

The main goal of the application consisted on the prediction of the amount of pure juice on a sample using absorbance values returned for the IR measurements. But the amount of data obtained for a sample by IR spectrometry is huge, so the direct application of mathematical and/or computational methods (although possible) requires a lot of time. Accordingly, it is important to establish whether all raw data provided relevant information for sample differentiation. Hence, the problem was an appropriate case for the use of variable selection techniques.

Previous to variable selection construction of data sets for both model development and validation was required. Thus, samples with different amounts of pure apple juice were prepared at the laboratory. Besides, 23 apple juice-based beverages sold in Spain were analysed (the declared amount of juice printed out on

Table 1. Low and high concentrations dataset

| Juice Concentration | 2% | 4% | 6% | 8% | 10% | 16% | 20% | Total |
|---------------------|----|----|----|----|-----|-----|-----|-------|
| Training | 19 | 17 | 16 | 22 | 21 | 20 | 19 | 134 |
| Validation | 1 | 1 | 13 | 6 | 6 | 6 | 6 | 39 |
| Commercial | 0 | 0 | 0 | 0 | 1 | 1 | 0 | 2 |

| Juice Concentration | 20% | 25% | 50% | 70% | 100% | Total |
|---------------------|-----|-----|-----|-----|------|-------|
| Training | 20 | 19 | 16 | 14 | 7 | 86 |
| Validation | 6 | 18 | 13 | 1 | 6 | 44 |
| Commercial | 0 | 2 | 0 | 0 | 19 | 21 |

their labels was used as input data). The samples were distributed in 2 ranges: samples containing less than 20% of pure juice and samples with more than 20% of pure apple juice (Table 1). IR spectra were obtained for all the samples.

This data was split in two datasets to extract the rules (ANN training) and to validate them. The commercial samples were used to further check the performance of the model. It is worth noting that whenever a predicted value does not match that given on the labels of the commercial products it might be owing to either a true wrong performance of the model (classification error) or an inaccurate labelling of the commercial beverage.

Classification Test Considering all the Original Variables

First test involved all variables given by IR spectroscopy. A dedicated ANN used all the absorbances of the training data to obtain a classification model. Later, the classification results obtained with this model will be used as a reference to compare the performance of the proposals over the same data.

Different parametric classification techniques (PLS, SIMCA, Potential Curves, etc.) were used too (Gestal, Gómez-Carracedo, Andrade, Dorado, Fernández, Prada, & Pazos, 2004), with very similar results. But the best results were achieved using ANN, which will be very useful to address the variable selection issue employing GA with fitness functions based on ANN. The accuracy of the reference method is shown in Table 2.

An exhaustive study of the results of the different classification models allowed us to conclude that the

set of samples with low (2-20%) percentages of juice was far more complex and difficult to classify than the samples with higher percentages (25-100%). Indeed, the number of errors was usually higher for the 2-20% range both in calibration and validation. Classification of the commercial samples agreed quite fine with the percentages of juice declared into the labels, but for a particular sample. When that sample was studied in detail it was observed that its spectrum was slightly different from the usual ones. This suggested that the juice contained an unusually high amount of added sugar(s).

VARIABLE SELECTION APPROACHES

Variable selection processes were performed to optimize the ANN classifications.

First, two simple approaches will be briefly described: Pruned and Fixed Search. Both approaches are based on a traditional GA and both use ANN to evaluate fitness. As the results will show, both techniques offer good solutions but present a common problem: an execution of each method provides only a solution (discarding any other possible optimal one). This was addressed with the two more advanced approaches described in the next sections.

Regardless of the variable selection approach, a GA will guide the search by evaluating the prediction capabilities of each ANN model developed employing different sets of IR variables. The problem that has to be solved is to find out a small set of IR variables that, when combined with an ANN model, classifies

Table 2. Classification with ANNs using all the variables

| | | | |
|---|------------------------------|--------------------------------|------------------------------|
| Low Concentrations | Training (134) 134 (100%) | Validation (39) 35 (89.74%) | Comercial (2) 2 (100%) |
| ANN Configuration for low concentrations Topology: 176 / 50 / 80 / 5 learning rate: 0.0005 stop criterion: mse=5 or epochs=500.000 | | | |
| High Concentrations | Training (86) 86 (100%) | Validation (44) 43 (97.72%) | Commercial (21) 21 (100%) |
| ANN Configuration Topology: 176 / 8 / 5 / 5 learning rate: 0.0005 stop criterion: mse=1 or epochs=500.000 | | | |

apple juice-based beverages properly (according to the amount of pure apple juice they contain).

Any time a subset of IR variables is proposed, the associated absorbance values are used as input patterns to the ANN. So, ANN will consider as much input processing elements (PEs) as variables. The output layer has one PE per category (6 for the lower range and 5 for the high ones). After several previous trials considering several hidden layers (from 1 to 4), each with different PEs (from 1 to 50), a compromise was established between the final fitness level reached by the ANN and the time required to its training. This compromise was essential because although better results were obtained with more hidden layers the time required for training was much higher as well. Then, it was decided not to extensively train the net but to get a good approximation to its real performance and elucidate whether the input variables are really suitable to accurately classify the samples.

The goal is to determine which solutions, among those provided by the GA, represent good starting points to perform more exhaustive training. Therefore, it would be enough to extend the ANN learning up to the point where it starts to converge. For this particular problem, convergence started after 800 cycles; to warrant it, 1000 iterations were fixed.

Next, each of the most promising solutions are used as inputs to an external ANN intended to provide the final classification results.

Pruned Search

This approach starts by considering all variables where from groups of variables are gradually discarded. The GA will steadily reduce the amount of variables that characterise the objects, until an optimal subset that allows for an overall satisfactory classification is obtained. This is used to classify the samples, and the results are used to determine how relevant the discarded wavenumbers were for the classification. This process can be continued as long as the classification results are equal, or at least similar, to those obtained using the overall set of variables. Therefore, the GA determines how many and which wavenumbers will be selected for the classification.

In this approach, each individual in the genetic population is described by n genes, each representing one variable. With a binary encoding each gene might be either 0 or 1, indicating whether the gene is active or

not and, therefore, if the variable should be considered for classification.

The evaluation function has to guide the pruning process on getting individuals with a low number of variables. To achieve this, the function should help those individuals that, besides classifying accurately, make use of fewer variables. In this particular case a factor proportional to the percentage of active genes was defined to multiply the MSE obtained by the ANN, so that individuals with less active genes – and with a similar classification performance – will have a higher fitness and consequently a higher probability of survival.

Table 3 shows the results of several runs of Pruned Search approach. It is worth noting that each solution was extracted from a different execution and that, within the same execution, only one solution provided valid classification rates. As it can be noted, classification results were very similar although the variables used to perform the classifications were different.

These ANN models were obtained are slightly worse than those obtained using 176 wavenumbers, although the generalization capabilities of the best ANNs model were quite satisfactory as there was only one error when the commercial beverages were classified.

Fixed Search

This approach uses a real codification in the chromosome of the genetic individuals. The genetic population consists of individuals with n genes, where n is the amount of wavenumbers that are considered sufficient for the classification according to some external criterion. Each gene represents one of the 176 wavenumbers considered in the IR spectra. The GA will find out the n -variables subsets yielding the best classification models. The number of variables is predefined in the genotype.

As the final number of variables has to be decided in advance, some external criterion is needed. In order to simplify comparison of the results, the final number of variables was defined by the minimum number of principal components which can describe our data set, they were two.

Since the amount of wavenumbers remains constant in the course of the selection process, this approach defines the fitness of each genetic individual as the mean square error reached by the ANN at the end of the training process.

Table 3. Classification with pruned search

| Low Concentrations | Training (134) | Validation (39) | Comercial (2) |
|---|----------------|-----------------|---------------|
| Run1: Selected Variables [42 77] | 129 (96.27%) | 23 (58.97%) | 1 (50%) |
| Run2: Selected Variables [52 141] | 115 (85.82%) | 22 (56.41%) | 0 (0%) |
| Run3: Selected Variables [102 129] | 124 (92.54%) | 25 (64.10%) | 0 (0%) |
| ANN Configuration for low concentrations Topology: 2 / 10 / 60 / 7 learning rate: 0.0001 stop criterion: mse=5 or epochs=500.000 | | | |
| High Concentrations | 86 | 43 | 21 |
| Run1: Selected Variables [42 77] | 83 (96.51%) | 34 (79.07%) | 21 (100%) |
| Run2: Selected Variables [52 141] | 82 (95,35%) | 35 (81.40%) | 20 (95.24%) |
| Run3: Selected Variables [102 129] | 83 (96.51%) | 33 (76.74%) | 21 (100%) |
| ANN Configuration Topology: 2 / 10 / 60 / 5 learning rate: 0.0001 stop criterion: mse=1 or epochs=500.000 | | | |

Table 4 shows the results of several runs of Pruned Search approach. Again, note that each run provides only a solution.

A problem was that the genetic individuals contains only two genes. Hence, any crossover operator will use the unique available crossing point (between the genes) and only half of the information from each parent will be transmitted to its offspring. This converts the Fixed Search approach into a “random search” when only two genes constituted the chromosome.

Hybrid Two-Population Genetic Algorithm

The main disadvantage of non-multimodal approaches is that they discard local optimal solutions because a final or global solution is preferred. But there are situations where the final model has to be extracted

after analysing different similar solutions of the same problem.

For example, after analysing the different solutions provided by one execution of the classification task with Hybrid Two-Population Genetic Algorithm (Rabuñal, Dorado, Gestal & Pedreira, 2005) it was obtained three valid (and similar) models (Table 5). Furthermore the results were clearly superior to those obtained with the previous alternatives. But, the most important, it was observed that the solutions concentrated along specific spectral areas (around the 88 wavenumber). It would not be possible with the previous approaches. This approach will be studied deeply on a dedicated chapter (Finding multiple solutions with GA in multimodal problems) and no more details will be presented here.

Table 4. Classification with fixed search

| Low Concentrations | Training (134) | Validation (39) | Comercial (2) |
|---|----------------|-----------------|---------------|
| Run1: Selected Variables [12 159] | 125 (93.28%) | 23 (58.97%) | 0 (0%) |
| Run2: Selected Variables [23 67] | 129 (96.27%) | 26 (66.66%) | 1 (50%) |
| Run3: Selected Variables [102 129] | 129 (96.27%) | 25 (64.10%) | 0 (0%) |
| ANN Configuration for low concentrations Topology: 2 / 10 / 60 / 7 learning rate: 0.0001 stop criterion: mse=5 or epochs=500.000 | | | |
| High Concentrations | 86 | 43 | 21 |
| Run1: Selected Variables [12 159] | 82 (95.35%) | 31 (72.09%) | 19 (90.47%) |
| Run2: Selected Variables [23 67] | 81 (94.18%) | 31 (72.09%) | 19 (90.47%) |
| Run3: Selected Variables [102 129] | 81 (94.18%) | 33 (76.74%) | 21 (100%) |
| ANN Configuration Topology: 2 / 10 / 60 / 5 learning rate: 0.0001 stop criterion: mse=1 or epochs=500.000 | | | |

FUTURE TRENDS

A next natural stage should be to consider multimodal approaches. Evolutionary Computation provides useful tools like fitness sharing, crowding... which should be compared to the hybrid two populations approach. Research is needed to implement criteria to allow the GA to stop when a satisfactory low number of variables is found.

Another suitable option should be include more scientific information within the system to guide the search. For example, a final user would provide a description of the ideal solution in terms of efficiency, data acquisition cost, simplicity, etc. All these parameters may be used as targets in a multiobjective Genetic Algorithm intended to provide the best variable subset complying with all the requirements.

CONCLUSION

Several conclusions can be drawn for variable selection tasks:

First, satisfactory classification results can be obtained from reduced sets of variables extracted using quite different techniques, all based on the combination of GA and ANN.

Best results were obtained using a multimodal GA (the hybrid two population approach), as it was expected, based on its ability to maintain the genetic individuals homogeneously distributed over the search space. Such diversity not only induces the appearance of optimal solutions, but also avoids the search to stop on a local minimum. This option does not provide only a solution but a group of them, with similar fitness. This allows scientists to select a solution with a sound chemical background and extract additional information.

KEY TERMS

Absorbance: Function (usually logarithmic) of the percentage of transmission of a wavelength of light through a liquid.

Artificial Neural Network: Interconnected group of artificial neurons that uses a mathematical or computational model for information processing. They are based on the function of biologic neurons. It involves a group of simple processing elements (the neurons) which can exhibit complex global behaviour, as result of the connections between the neurons.

Evolutionary Technique: Technique which provides solutions for a problem guided by biological principles such as the survival of the fittest. These techniques start from a randomly generated population which evolves by means of crossover and mutation operations to provide the final solution.

Knowledge Extraction: Explication of the internal knowledge of a system or set of data in a way that is easily interpretable by the user.

Search Space: Set of all possible situations of the problem that we want to solve could ever be in. Combination of all the possible values for all the variables related with the problem.

Spectroscopy (Spectrometry): Production, measurement and analysis of electromagnetic spectra produced as a result of the interactions between electromagnetic radiation and matter, such as emission or absorption of energy.

Spectrum: Intensity of a electromagnetic radiation across a range of wavelengths. It represents the intensity of emitted or transmitted energy versus the energy of the received light.

Variable Selection: Selection of a subset of relevant variables (features) which can describe a set of data.

Evolutionary Computing Approach for Ad-Hoc Networks

INTRODUCTION

Wireless ad-hoc networks are infrastructureless networks in which heterogeneous capable nodes assemble together and start communicating without any backbone support. These networks can be made truly dynamic and the nodes in these networks can move about freely while connecting and disconnecting with other nodes in the network. This property of ad-hoc networks to self-organize and communicate without any extrinsic support gives them tremendous flexibility and makes them perfect for applications such as emergencies, crisis-management, military and healthcare.

For example, in case of emergencies such as earthquakes, often most of the existing wired network infrastructure gets destroyed. In addition, since most of the wireless networks such as GSM and IEEE 802.11 wireless LAN use wired infrastructure as their backbone, often they are also rendered useless. In such scenarios, ad-hoc networks can be deployed swiftly and used for coordinating relief and rescue operations. Ad-hoc networks can be used for communication between various stations in the battle-field, where setting up a wired or an infrastructure-based network is often considered impractical.

Though a lot of research has been done on ad-hoc networks, a lot of problems such as security, quality-of-service (QoS) and multicasting need to be addressed satisfactorily before ad-hoc networks can move out of the labs and provide a flexible and cheap networking solution.

Evolutionary computing algorithms are a class of bio-inspired computing algorithms. Bio-inspired computing refers to the collection of algorithms that use techniques learnt from natural biological phenomena

and implement them to solve a mathematical problem (Olario & Zomaya, 2006). Natural phenomena such as evolution, genetics, and collective behavior of social organisms and functioning of a mammalian brain teach us a variety of techniques that can be effectively employed to solve problems in computer science which are inherently tough.

In this Chapter and the chapter entitled, “Swarm Intelligence Approach for Wireless Ad Hoc Networks” of this book, we present some of the currently available important implementations of bio-inspired computing in the field of ad-hoc networks. This chapter looks at the problem of optimal clustering in ad-hoc networks and its solution using Genetic Programming (GP) approach. The chapter entitled, “Swarm Intelligence Approaches for Wireless Ad Hoc Networks” of this book, continues the same spirit and explains the use of the principles underlying Ant Colony Optimization (ACO) for routing in ad-hoc networks.

BACKGROUND

The first infrastructureless network was implemented as packet radio (Toh, 2002). It was initiated by the Defense Advanced Research Projects Agency (DARPA) in 1970s. By this time the ALOHA project (McQuillan & Walden, 1977) at the University of Hawaii had demonstrated the feasibility of using broadcasting for sending / receiving the data packets in single-hop radio networks. ALOHA later led to the development of Packet Radio Network (PRNET), which was a multi-hop multiple-access network, under the sponsorship of Advanced Research Projects Agency (ARPA). PRNET had the design objectives similar to

the current day ad-hoc networks such as flow and error control over multi-hop communication route, deriving and maintaining network topology information and mechanism to handle router mobility and power and size requirements, among others. However, since the electronic devices were huge then, the packet radios were not easily movable, leading to limited mobility. In addition, the network coverage was slow and since Bellman-Ford's shortest path algorithm was used for routing, transient loops were present. Since then, a lot of research has been done on ad-hoc networks and a number of routing algorithms have been developed which provide far greater performances and are loop free. The rapid development of silicon technology has also led to ever shrinking devices with increasing computation power. Ad-hoc networks are deliberated for use in medical, relief-and-rescue, office environments, personal networking, and many other daily life applications.

Bio-inspired algorithms, to which the evolutionary computing approaches such as genetic algorithms belong, have been around for more than past 50 years. In fact, there have been evidences that suggest that the Artificial Neural Networks are rooted in the unpublished works of A. Turing (related to the popular *Turing Machine*) (Paun, 2004). Finite Automata Theory was developed about a decade after that based on the neural modeling. This ultimately led to the area that is currently known as Neural Computing. This can effectively be called as the initiation of bio-inspired computing. Since then, techniques such as GP, Swarm Intelligence and Ant Colony Optimization and DNA computing have been researched and developed as nature continues to inspire us and show us the way for solving the most complex problems known to man.

MAIN FOCUS OF THE CHAPTER

This chapter and the the chapter entitled, "Swarm Intelligence Approaches for Wireless Ad Hoc Networks" of this book, in combination, present an introduction to various bio-inspired algorithms and describe their implementation in the area of wireless ad-hoc networks. This chapter primarily presents the GP approach to ad-hoc networks. We first give a general introduction to GP and explain the concepts of genes and chromosomes. We also explain the stochastic nature of GP and the process of mutation and crossover to provide optimal

solution to the problem using the GP approach. We then present the Weighted Clustering Algorithm given by (Chatterjee, Das & Turgut, 2002) that are used for clustering of nodes in mobile ad-hoc networks, as an instantiation of this approach.

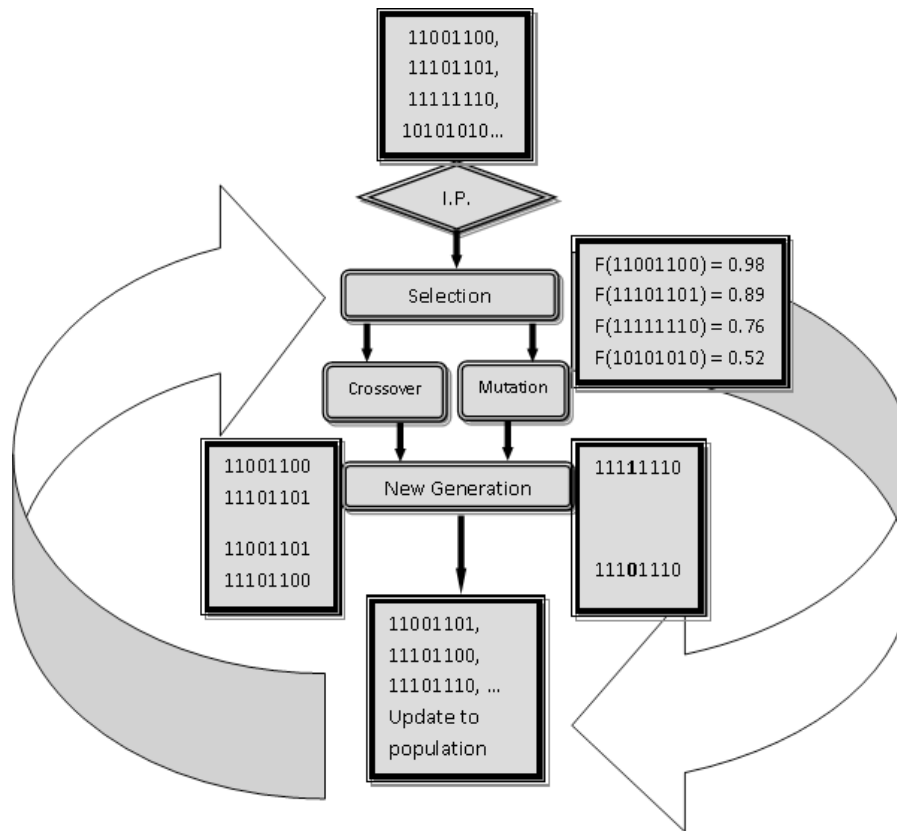

GP

GP is a popular bio-inspired computing method. The concepts in genetic algorithms are inspired by the phenomenon of life and evolution itself. Life is a problem whose solution includes retaining those who have strong enough characteristics to survive in the environment and discarding the others. This exquisite process can provide solutions to complex analytical problems awaiting the most "fitting" result.

The basics include the role of chromosomes and genes. Chromosomes carry the genes which contain the parameters/characteristics that need to be optimized. Hence, GP starts with declaration of data structures that form the digital chromosomes. These digital chromosomes contain genetic information where each gene represents a parameter to be optimized. The gene could be represented as a single bit, which could be '1' (ON) or '0' (OFF). So, a chromosome is a sequence of 1's and 0's and a parameter is either totally present or totally absent. Other abstractions could represent the presence of a parameter in relative levels. For instance, a gene could be represented using 5 bits where the magnitude of the binary number tells about the magnitude of the presence of a parameter in the range '0' (00000) to '31' (11111).

First, these digital chromosomes are created using stochastic means. Then their fitness is tested either by static calculation of fitness using some method or dynamically by modelling fights between the chromosomes. The chromosomes with a set level of fitness are retained and allowed to produce a new generation of chromosomes. This can be done either by genetic recombination that is new chromosomes are produced with combination of present chromosomes, or by mutation, that is new chromosomes are produced by randomly producing changes in present chromosomes. This process of testing for fitness and creating new generations is repeated until the fittest chromosomes are deemed as optimized enough for the task, which the genetic algorithm was created for. The process is described in Figure 1.

Figure 1. Genetic algorithm

Genetic algorithms begin with a stochastic process and arrive at an optimized solution and are time consuming.. Hence, they are generally used for solving complex problems. As mentioned by Ashby (1962), self organization is one of these complex problems. Self organization is the problem where the components of a multi-component system achieve (or try to achieve) a common goal without any centralized or distributed control. The organization is generally done by changing the direct environment which can be adapted by the various system components and hence affect the behaviour of these components.

As has been mentioned, “Self-organization is especially important in ad-hoc networking because of the spontaneous interaction of multiple heterogeneous components over wireless radio connections without human interaction” (Murthy & S., 2004).

Dressler (2006) gives the following list of self organization capabilities:

- Self-healing: The system should be able to detect and repair the failures cause by overloading, component malfunctioning or system breakdown.
- Self-configuration: The system should be able to generate adequate configurations including connectivity, quality of service etc. as required in the existing scenario
- Self-management: The system should be able to maintain devices and in turn the network depending on the set configuration parameters.
- Self-optimization: The system should be to make an optimal choice of methods depending on the system behaviour .

- Adaptation: The system should dynamically adapt to the changing environment conditions, for example, change in node positions, change in number of nodes in the network etc.

Genetic algorithms have been used extensively in robotics, electronic circuit design, natural language processing, game theory, multi-model search, computer network topology design among many other applications.

In the context of wireless ad-hoc networks, genetic algorithms have been used in solving shortest path routing problem (Ahn & Ramakrishna, 2002), QoS path discovery (Fu, Li & Zhang, 2005), developing broadcasting strategy (Alba, Dorronsoro, Luna, Nebro & Bouvry, 2005), QoS routing (Barolli, Koyama & Shiratori, 2003), among others. In the interest of brevity, we present below only one representative application of the use of genetic algorithms to solve problems in ad-hoc networks.

Weighted Clustering Using Genetic Algorithm

Nodes in ad-hoc networks are sometimes grouped into various clusters with each cluster having a cluster-head. Clustering aims at introducing a kind of organisation in ad-hoc networks. This leads to better scalability of networks resulting in better utilisation of resources in larger networks. A cluster-head is responsible for the formation of clusters and maintenance of clusters in ad-hoc networks. Several clustering mechanisms have been proposed for ad-hoc networks, like Lowest-ID (Ephremides, Wieselthier & Baker, 1987), Highest Connectivity (Gerla & Tsai, 1995) Distributed Mobility-Adaptive Clustering (DMAC) (Basagni, 1999), Distributed Dynamic Clustering Algorithm (McDonald & Znati, 1999) and Weight-Based Adaptive Clustering Algorithm (WBACA) (Dhurandher & Singh, 2007).

Weighted Clustering Algorithm (WCA) (Chatterjee, Das and Turgut, 2002) is a popular clustering algorithm which selects a cluster-head on the basis of node mobility, battery-power, connectivity, distance from neighbour and degree of connectivity. Weights are assigned to each parameter and a combined weighted metric W_v is calculated as shown by Equation (1) (Chatterjee, Das and Turgut, 2002). Within certain constraints, nodes with minimum W_v are selected as the cluster-head.

$$W_v = w_1 \Delta_v + w_2 D_v + w_3 M_v + w_4 P_v \quad (1)$$

In Equation (1),

Δ_v signifies the difference between optimal and actual connectivity of a node.

D_v signifies the sum of distances with all the neighbouring nodes.

M_v is the running average of the speed of the node.

P_v signifies the time that the node has acted as a cluster-head.

w_1, w_2, w_3 and w_4 are relative weights given to different parameters.

It should be noted that (Chatterjee, Das and Turgut, 2002):

$$w_1 + w_2 + w_3 + w_4 = 1 \quad (2)$$

A genetic algorithm-based approach was presented by the designers of WCA (Chatterjee, Das, & Turgut, 2002). The sub-optimal solutions are mapped to chromosomes and given as input to produce best solutions using genetic techniques. This leads to better performance and more evenly balanced load sharing. The basic building blocks of the algorithm are given below:

Initial Population: A candidate solution which acts as a chromosome can be represented as shown in Figure 6. This initial population set is generated randomly by arranging the nodes in strings and then traversing this string. A node which is not a cluster-head and is not a neighbour of a cluster-head (and hence, part of an existing cluster) is chosen as a cluster head if it has less than δ (a pre-defined constant) neighbours. δ is chosen such as to prevent a cluster-head with more than optimal neighbour causing over-loading at cluster-heads.

Objective Fitness Function: Fitness value of a chromosome can be calculated as the sum of W_v of the contained genes. All nodes present at a gene [1] are analysed. If a node is not a cluster-head or a member of a cluster-head and has a node degree less than MAX_DEGREE, it is added to the cluster-head list and its W_v value is added to the total sum. For remaining nodes in the network, if the node is not a cluster-head or a member of other cluster-head, its W_v value is added to the sum and

the node is added to the cluster-head list. Lesser the sum of the W_v values of the genes, the higher is the fitness value of the chromosome.

Crossover: The crossover rate is 80 %. The authors used a technique called X_Over1 (Chatterjee,

Das, & Turgut, 2002) as the crossover technique for the genetic implementation.

Mutation: Mutation introduces randomness into the solution space. If mutation rate is low, there is a chance of the solution converging to a non-optimal

Figure 3. Genetic algorithm for weighted clustering in ad-hoc networks¹

```
Algo_genetic_cluster{
    Generate initial population randomly, with population size = number of
    nodes
    do{
        while(new_pool_size < old_pool_size){
            select chromosomes using Roulette wheel
            method;
            apply crossover using X_Over1;
            apply mutation by swapping genes;
            find fitness value of all the chromosomes;
            replace through appending;
        }
    }
```

solution space. Hence, mutation is a very important step in genetic computations. In the stated algorithm, the inventors used swapping for the process of mutation. Two genes of a chromosome were selected randomly and swapped. Mutation rate used is 10%.

Selection Criteria: As mentioned earlier, chromosomes with lower values of W_v are considered fitter. Roulette wheel method is used for selection in accordance with the fitness values of these chromosomes.

Elitism: If the new generation produced has fitness value better than the best fitness value of the previous generation, than the best solution is replaced by the new generation. Since the best solutions of a generation are replaced, this step helps avoid the local maxima of the solution space and move towards the global maxima.

Replacement: This method states that, during replacement, the best solution of a generation is appended to the solution set of the next generation. This step helps in preserving the best solution during genetic operations.

Using these building functions, the genetic algorithm for the weighted clustering algorithm was given. This algorithm is given in Figure 3.

CONCLUSION

This article presented an overview of an evolutionary computing approach using GP and their application to wireless ad-hoc networks, both of which are currently “hot” topics amongst the computer science and networking research community. The intention of writing this article was to show how one could “marry” together concepts from GP with ad-hoc networks to arrive at interesting results. In particular we reviewed the WCA algorithm (Chatterjee, Das and Turgut, 2002) which uses GP for clustering of nodes in ad-hoc networks.

KEY TERMS

Bio-Inspired Algorithms: Group of algorithms modelled on the observed natural phenomena which are employed to solve mathematical problems.

Chromosome: A proposed solution to a problem which is represented as a string of bits and can mutate and cross-over to create a new solution.

Clustering: Grouping the nodes of an ad hoc network such that each group is a self-organized entity

having a cluster-head which is responsible for formation and management of its cluster.

Cross-Over: Genetic operation which produces a new chromosome by combining the genes of two or more parent chromosome.

Fitness Function: A function which maps the subjective property of a fitness of a solution to an objective value which can be used to arrange different solutions in the order of their suitability as final or intermediate solution.

Genes: Genes are building blocks of chromosomes and represent the parameters that need to be optimized.

Genetic Algorithms: The algorithms that are modelled on the natural process of evolution. These algorithms employ methods such as crossover, mutation and natural selection and provide the best possible solutions after analyzing a group of sub-optimal solutions which are provided as inputs.

Initial Population: Set of sub-optimal solutions which are provided as inputs to a genetic algorithm and from which an optimal solution evolves.

Mobile Ad-Hoc Network: A multi-hop network formed by a group of mobile nodes which co-operate among each other to achieve communication, without requiring any supporting infrastructure.

Mutation: Genetic operation which randomly alters a chromosome to produce a new chromosome adding new solution to the solution-set.

Evolutionary Grammatical Inference

Ernesto Rodrigues

Federal University of Technology, Brazil

Heitor Silvério Lopes

Federal University of Technology, Brazil

INTRODUCTION

Grammatical Inference (also known as grammar induction) is the problem of learning a grammar for a language from a set of examples. In a broad sense, some data is presented to the learner that should return a grammar capable of explaining to some extent the input data. The grammar inferred from data can then be used to classify unseen data or provide some suitable model for it.

The classical formalization of **Grammatical Inference** (GI) is known as Language Identification in the Limit (Gold, 1967). Here, there are a finite set S_+ of strings known to belong to the language L (the positive examples) and another finite set S_- of strings not belonging to L (the negative examples). The language L is said to be identifiable in the limit if there exists a procedure to find a grammar G such that $S_+ \subseteq L(G)$, $S_- \not\subseteq L(G)$ and, in the limit, for sufficiently large S_+ and S_- , $L = L(G)$. The disjoint sets S_+ and S_- are given to provide clues for the inference of the production rules P of the unknown grammar G used to generate the language L .

Grammatical inference include such diverse fields as speech and natural language processing, gene analysis, pattern recognition, image processing, sequence prediction, information retrieval, cryptography, and many more. An excellent source for a state-of-the art overview of the subject is provided in (de la Higuera, 2005).

Traditionally, most work in GI has been focused on the inference of regular grammars trying to induce finite-state automata, which can be efficiently learned. For context free languages some recent approaches have shown limited success (Starckie, Costie & Zaanen, 2004), because the search space of possible grammars is infinite. Basically, the parenthesis and palindrome languages are common test cases for the effectiveness of grammatical inference methods. Both languages are

context-free. The parenthesis language is deterministic but the palindrome language is nondeterministic (de la Higuera, 2005).

The use of evolutionary methods for context-free grammatical inference are not new, but only a few attempts have been successful.

Wyard (1991) used Genetic Algorithm (GA) to infer grammars for the language of correctly balanced and nested parentheses with success, but fails on the language of sentences containing the same number of a 's and b 's ($a^n b^n$ language). In another attempt (Wyard, 1994), he obtained positive results on the inference of two classes of context-free grammars: the class of n -symbol palindromes with $2 \leq n \leq 4$ and a class of small natural language grammars.

Sen and Janakiraman (1992) applied a GA using a pushdown automata to the inference and successfully learned the $a^n b^n$ language and the parentheses balancing problem. But their approach does not scale well.

Huijsen (1994) applied GA to infer context-free grammars for the parentheses balancing problem, the language of equal numbers of a 's and b 's and the even-length 2-symbol palindromes. Huijsen uses a "markerbased" encoding scheme with has the main advantage of allowing variable length chromosomes. The inference of regular grammars was successful but the inference of context-free grammars failed.

Those results obtained in earlier attempts using GA to context-free grammatical inference were limited. The first attempt to use Genetic Programming (GP) for grammatical inference used a pushdown automata (Dunay, 1994) and successfully learned the parenthesis language, but failed for the $a^n b^n$ language.

Korkmaz and Ucoluk (2001) also presented a GP approach using a prototype theory, which provides a way to recognize similarity between the grammars in the population. With this representation, it is possible to recognize the so-called building blocks but the results are preliminary.

Javed and his colleagues (2004) proposed a Genetic Programming (GP) approach with grammar-specific heuristic operators with non-random construction of the initial grammar population. Their approach succeeded in inducing small context-free grammars.

More recently, Rodrigues and Lopes (2006) proposed a hybrid GP approach that uses a confusion matrix to compute the fitness. They also proposed a local search mechanism that uses information obtained from the sentence parsing to generate a set of useful productions. The system was used for the parenthesis and palindromes languages with success.

BACKGROUND

A formal language is usually defined as follows. Given a finite alphabet Σ of symbols, we define the set of all strings (including the empty string ϵ) over Σ as Σ^* . Thus, we want to learn a language $L \subset \Sigma^*$. The alphabet Σ could be a set of characters or a set of words. The most common way to define a language is based on grammars which gives rules for combining symbols and to produce the all sentences of a language.

A grammar is defined by a quadruple $G = (N, \Sigma, P, S)$, where N is an alphabet of nonterminal symbols, Σ is an alphabet of terminal symbols such that $N \cap \Sigma = \emptyset$, P is a finite set of production rules of the form $\alpha \rightarrow \beta$ for $\alpha, \beta \in (N \cup \Sigma)^*$ where $*$ represents the set of symbols that can be formed by taking any number of them, possibly with repetitions. S is a special nonterminal symbol called the start symbol.

The language $L(G)$ produced from grammar G is the set of all strings consisting only of terminal symbols that can be derived from the start symbol S by the application of production rules. The process of deriving strings by applying productions requires the definition of a new relation symbol \Rightarrow . Let $\alpha X \beta$ be a string of terminals and nonterminals, where X is a nonterminal. That is, α and β are strings in $(N \cup \Sigma)^*$, and $X \in N$. If $X \rightarrow \varphi$ is a production of G , we can say $\alpha X \beta \Rightarrow \alpha \varphi \beta$. It is important to say that one derivation step can replace any nonterminal anywhere in the string. We may extend the \Rightarrow relationship to represent one or many derivation steps. We use a $*$ to denote more steps. Therefore, we formally define the language $L(G)$ produced from grammar G as $L(G) = \{ w \mid w \in \Sigma^*, S \Rightarrow^* w \}$.

More details about formal languages and grammars can be found in textbooks such as Hopcroft et al (2001).

The Chomsky Hierarchy

Grammars are classified according to the form of the production rules used. They are commonly grouped into a hierarchy of four classes, known as the **Chomsky hierarchy** (Chomsky, 1957).

- *Recursively enumerable languages*: a grammar is unrestricted, and its productions may replace any number of grammar symbols by any other number of grammar symbols. The productions are of the form $\alpha \rightarrow \beta$ with $\alpha, \beta \in (N \cup \Sigma)^*$.
- *Context-sensitive languages*: they have grammars with productions that replace a single nonterminal by a string of symbols, whenever the nonterminal occurs in a specific *context*, i.e., has certain left and right neighbors. These productions are of the form $\alpha A \gamma \rightarrow \alpha \beta \gamma$, with $A \in N$ and $\alpha, \beta, \gamma \in (N \cup \Sigma)^*$. A is replaced by β if it occurs between α and γ .
- *Context-free languages*: in this type, grammars have productions that replace a single nonterminal by a string of symbols, regardless of this nonterminal's context. The productions are of the form $A \rightarrow \alpha$ for $A \in N$ and $\alpha \in (N \cup \Sigma)^*$; thus A has no context.
- *Regular languages*: they have grammars in which a production may only replace a single nonterminal by another nonterminal and a terminal. The productions are of the form $A \rightarrow B\alpha$ or $A \rightarrow \alpha B$ for $A, B \in N$ and $\alpha \in \Sigma^*$.

It is sometimes useful to write a grammar in a particular form. The most commonly used in grammatical inference is the Chomsky Normal Form. A CFG G is in Chomsky Normal Form (CNF) if all production rules are of the form $A \rightarrow BC$ or $A \rightarrow \alpha$ for $A, B, C \in N$ and $\alpha \in \Sigma$.

The Cocke-Younger-Kasami Algorithm

To determine whether a string can be generated by a given context-free grammar in CNF, the Cocke-Younger-Kasami (CYK) algorithm can be used. This

algorithm is efficient and it has complexity $O(n^3)$ where n is the sentence length .

In the CYK algorithm, first a triangular table that tells whether the string w is in $L(G)$ is constructed. The horizontal line corresponds to the positions of the string $w = a_1 a_2 \dots a_n$. The table entry V_{rs} is the set of variables $A \in P$ such that $A \Rightarrow^* a_r a_{r+1} \dots a_s$. We are interested in whether the start symbol S is in the set V_{1n} because that is the same as saying $S \Rightarrow^* a_1 a_2 \dots a_n$ or $S \Rightarrow^* w$, i. e., $w \in L(G)$.

To fill the table, we work row-by-row upwards. Each row corresponds to one length of substrings; the bottom row is for strings of length 1, the second-from-bottom row for strings of length 2 and so on, until the top row corresponds to the one substring of length n which is w itself. The pseudocode is in Figure 1.

Genetic Programming

Genetic Programming (GP) is an evolutionary technique used to search over a huge state space of structured representations (computer programs). Each program represents a possible solution written in some language. The GP algorithm can be summarized in Figure 2 (Koza, 1992).

The evaluation of a solution is accomplished by using a set of training examples known as fitness cases which, in turn, is composed by sets of input and output data. Usually, the fitness is a measure of the deviation between the expected output for each input and the computed value given by GP (Banzhaf, Nordin, Keller & Francone, 2001).

Figure 1. The CYK algorithm

```

For r = 1 to n do
   $V_{r1} = \{ A \mid A \rightarrow a_r \in P \}$ 

For s = 2 to n do
  For r = 1 to n-s+1 do
     $V_{rs} = \emptyset$ 
    For k = 1 to s-1 do
       $V_{rs} = V_{rs} \cup \{ A \mid A \rightarrow BC \in P, B \in V_{rk} \text{ and } C \in V_{r+k, s-k} \}$ 

```

Figure 2. The GP algorithm

```

Generate Initial Population Randomly
While not (Stopping Condition)
  begin
    Evaluate the fitness of each individual
    Select individuals according to their fitness
    Modify them by applying genetic operators
  end
Returns the best individual found

```

There are two main selection methods used in GP: fitness proportionate and tournament selection. In the fitness proportionate selection, programs are selected randomly with probability proportional to its fitness. In the tournament selection, a fixed number of programs are taken randomly from the population and the one with the best fitness in this group is chosen. In this work, we use the tournament selection.

Reproduction is a genetic operator that simply copies a program to the next generation. Crossover, on the other hand, combines parts of two individuals to create two new ones. Mutation changes randomly a small part of an individual.

Each run of the main loop of GP creates a new generation of computer programs that substitutes the previous one. The evolution is stopped when a satisfactory solution is achieved or a predefined maximum number of generations is reached.

A GRAMMAR GENETIC PROGRAMMING APPROACH

We present how a GP approach can be applied to the inference of context-free grammars. First, we discuss the representation of the grammars. The modification needed in the genetic operators are also presented. In the last section, the grammar evaluation are discussed.

Initial Population

It is possible to represent a CFG as a list of structured trees. Each tree represents a production with its

left-hand side as a root and the derivations as leaves. Figure 3 shows the grammar $G = (N, \Sigma, P, S)$ with $\Sigma = \{a, b\}$, $N = \{S, A\}$ and $P = \{S \rightarrow AS; S \rightarrow b; A \rightarrow SA; A \rightarrow a\}$.

The initial population can be created with random productions, provided that all the productions are reachable direct or indirectly starting with S .

Genetic Operators

The crossover operator is applied over a pair of grammars and works as follows. First, a production is chosen using a tournament selection. If the second grammar has no production with the same left-hand side of the production chosen, crossover is rejected. Otherwise, the productions are swapped.

The mutation operation is applied to a single selected grammar. A production is then chosen using the same mechanism of crossover. A new production, with the same left-hand side and with a randomly right-side, replaces the production chosen.

The crossover probability is usually high ($\approx 90\%$) and the mutation probability is usually low ($\approx 10\%$).

Unfortunately, using only the genetic operators mentioned, the convergence of the algorithm is not guaranteed. In our recently work, we demonstrated that the use of two local search operators is needed: an incremental learning operator (Rodrigues & Lopes, 2006) and an expansion operator (Rodrigues & Lopes, 2007). The first uses the information obtained from a CYK table to discover which production is missing to cover the sentence. The latter can expand the set of productions dynamically providing diversity.

Figure 3. An example of a CFG represented as a list of structured trees

The Incremental Learning Operator

This operator is applied before the evaluation of each grammar in the population. It uses the CYK table obtained from the parsing of positive examples to allow the creation of an useful new production. The pseudocode is in Figure 4.

Once this process is completed with success, hopefully, there will be a set of positive examples (possible all) recognized by the grammar. Although, there is no warranty that some negative examples will still remain being rejected by the grammar.

The Expansion Operator

This operator adds a new nonterminal to the grammar and generates a new production with this new nonterminal as a left-side. This new approach allows grammars to grow dynamically in size. To avoid a new useless production, a production with another non-terminal in the left-side and the new non-terminal in the right-side is generated. It is important to emphasize that the new operator adds two productions to the grammar.

This operator promotes diversity in the population that is required in the beginning of the evolutionary process.

Grammar Evaluation

In grammatical inference, we need to train the system with both positive and negative examples to avoid overgeneralization. Usually the evaluation is done counting the positive examples covered by a grammar in proportion to the total of positive examples. If the grammar cover some negative examples, it is penalized in some way.

In our recently work, we use a **confusion matrix** that is typically used in supervised learning (Witten & Frank, 2005). Each column of the matrix represents the number of instances predicted either positively or negatively, while each row represents real classification of the instances. The entries in the confusion matrix have the following meaning in the context of our study:

- TP is the number of positive instances recognized by the grammar.
- TN is the number of negative instances rejected by the grammar.
- FP is the number of negative instances recognized by the grammar.
- FN is the number of positive instances rejected by the grammar.

Figure 4. The incremental learning operator pseudocode

```

For each positive example
  Construct the CYK table with  $V_{rs}$ 
  If the example is not recognized
    If  $V_{1n}$  is not empty
      Then clone the root production changing
        the left-hand side by S.
    Else
      If  $V_{2,n-1}$  is not empty
        Then add production  $S \rightarrow V_{11} V_{2,n-1}$ 
      Else
        For  $s = n-1$  to  $n/2$  do
          begin
            If  $V_{1s}$  is not empty
              Then If  $V_{s+1, n-s}$  is not empty
                Then add production  $S \rightarrow V_{1s} V_{s+1, n-s}$ 
          end

```

There are a several measures that can be obtained from the confusion matrix. The most common is total accuracy that is obtained from the total of correct classified examples divided by the total number of instances. In this paper we used two other measures: specificity (Equation 1) and sensitivity (Equation 2). These measures evaluate how positive and negative examples are correctly recognized by the classifier.

$$\text{specificity} = \frac{\text{TN}}{\text{TN} + \text{FP}} \quad (1)$$

$$\text{sensitivity} = \frac{\text{TP}}{\text{TP} + \text{FN}} \quad (2)$$

The fitness is computed by the product of these measures leading to a balanced heuristic. This fitness measure was proposed by (Lopes, Coutinho & Lima, 1998) and widely used in many classification problems.

The use of confusion matrix provides a better evaluation of the grammars in the population, because grammars with the same accuracy rate usually has different values for specificity and sensitivity.

FUTURE TRENDS

The GP approach for the grammatical inference is based on the CYK algorithm and the confusion matrix. The preliminary results are promising but there are two problems that must be addressed.

The first is the that the solution found is not necessarily the smallest one. Depending on the run, the grammar inferred varies in size and, sometimes, it can be difficult to understand and may have useless or redundant production rules. Further work will focus on devising a mechanism able to favor shorter partial solutions.

The second is called “bloat”, the uncontrolled growth of the size of an individual in the population (Monsieurs & Flerackers, 2001). The use of an expansion operator may cause this undesirable behavior. Nevertheless, this behavior was not detected in the experiments because all useless productions are eliminated during the search.

CONCLUSION

This article proposes a GP approach for context-free grammar inference. In this approach, an individual is a list of structured trees representing their productions with their left-hand side as the root and the derivations as leaves. It uses a local search operator, named Incremental Learning, capable of adjusting each grammar according to the positive examples. It also uses an expansion operator which adds a new production to the grammar allowing the grammars to grow in size. This operator promotes diversity in the population that is required in the earlier generations.

The use of a local search mechanism that is capable of learning from examples promotes a fast convergence. The preliminary results demonstrated that the approach is promising.

KEY TERMS

CYK: A Cocke-Younger-Kasami algorithm used to determine whether the sentence can be generated by the grammar.

Evolutionary Computation: Large and diverse class of population-based search algorithms that is inspired by the process of biological evolution through selection, mutation and recombination. They are iterative algorithms that start with an initial population of candidate solutions and then repeatedly apply a series of the genetic operators.

Finite Automata: A model of behavior composed of a finite number of states, transitions between those states, and actions. They are used to recognize regular languages.

Genetic Algorithm: A type of evolutionary computation algorithm in which candidate solutions are represented typically by vectors of integers or bit strings, that is, by vectors of binary values 0 and 1.

Heuristic: Function used for making certain decisions within an algorithm; in the context of search algorithms, typically used for guiding the search process.

Local Search: A type of search method that starts at some point in search space and iteratively moves from position to neighbouring position using heuristics.

Pushdown Automata: A finite automaton that can make use of a stack containing data. They are used to recognize context-free language.

Search Space: Set of all candidate solutions of a given problem instance.

Evolutionary Robotics

INTRODUCTION

Evolutionary Robotics is a field of **Autonomous Robotics** where the controllers that implement behaviours are obtained through some kind of Evolutionary Algorithm. The aim behind this technique is to obtain controllers minimizing human intervention. This is very interesting in order to achieve complex behaviours without introducing a “human bias”. Sensors, body and actuators are usually different for a human being and for a robot, so it is reasonable to think that the best strategy obtained by the human designer is not necessarily the best one for the robot. This article will briefly describe Evolutionary Robotics and its advantages over other approaches to Autonomous Robotics as well as its problems and drawbacks.

BACKGROUND

The firsts modern attempts to obtain a **robot** that could be called “autonomous”, that is, with the ability of adapting to a non predefined environment and perform its tasks adequately, are from the late sixties and they basically tried to reproduce human reasoning in the robot. The reasoning process was divided into several steps (input data interpretation, environment modelling, planning and execution) that were performed sequentially. As time passed, robots were getting better thanks to better design and construction, more computational capabilities and improvements in the Artificial Intelligence techniques employed. But also some problems appeared and remained there: lack of reaction in real time, inability to handle dynamic environments and unmanaged complexity as desired behaviours become more complex.

In the late eighties a new approach, called **Behaviour Based Robotics**, was introduced. It emphasized the behaviour, no matter how it was obtained, as op-

posed to traditional (knowledge based) Autonomous Robotics where the emphasis was on modelling the knowledge needed to perform the behaviour. This new approach proposes a direct connection between sensors and actuators with no explicit environment modelling. Behaviour Based Robotics has proven to be very useful when implementing low level behaviours, but it has also shown problems when scaling to more complex behaviours. Phil Husbands (Phil Husbands et al., 1994) and Dave Cliff (Cliff et al., 1993a) have shown that it is not easy to design a system that connects sensors and actuators in order to achieve complex behaviours. Regardless of whether the system is monolithic (to design a complex system in just one step is never easy) or modular the design problem is difficult basically due to the fact that the possible interactions between modules grow exponentially. An additional problem is that human designed controllers for autonomous robots are not necessarily the best choice, sometimes they are simply not a good choice. A human designer cannot avoid perceiving the world with its own sensors and developing solutions for problems taking into account the perceptions and the actuations he / she can perform. Furthermore, humans tend to simplify and modularize problems and this is not always possible in complex environments.

Due to these drawbacks, in the early nineties some researchers started to use Evolutionary Algorithms in order to automatically obtain controllers for autonomous robots leading to a new robotics field: Evolutionary Robotics. Some examples of these research line are the papers by Irman Harvey (Harvey et al., 1993), Phil Husbands (Husbands et al., 1994), Dave Cliff (Cliff et al., 1993a) and Randall Beer and John Gallagher (Randall Beer and John Gallagher, 1992). The idea is very simple and very promising and, again, has shown it is very effective with simple behaviours. But, even if it solves some problems, it also has its own problems when dealing with complex behaviours. In the next sec-

tion we will talk about those problems and, in general, about the main aspects to take into account when using evolution in Autonomous Robotics.

EVOLUTIONARY ROBOTICS

The basis of Evolutionary Robotics is to use **evolutionary algorithms** to automatically obtain robot controllers. In order to do that, there are many decisions to be made. First of all, one must decide what to evolve (controllers, morphology, both?). Then, whatever is to be evolved has to be encoded in chromosomes. An evolutionary algorithm must be chosen. It has to be decided where and how to evaluate each individual, etc. These issues will be addressed in the following sections.

What to Evolve

The first decision to be made is what to evolve. The most common choice is to evolve controllers for a given robot, but we can also evolve the morphology or both things together. If we choose to evolve only the controllers, we also have to decide how they will be implemented. The most usual choices are artificial neural networks, fuzzy logic systems and classifier systems.

Classifier systems are made up of rules (the classifier set). Each rule consists of a set of conditions and a message. If the conditions are accomplished, a message can produce an action on an actuator and is stored in a message list. Sensor values are also stored in this message list. Messages in the message list may change the state of conditions, leading to a different set of activated rules. There is an apportionment of credit system that changes the strength for each rule and a rule discovery system, where a genetic algorithm generates new rules using existing rules in the classifier set and their strength. An example of classifier systems is the work of Dorigo and Colombetti (Colombetti et al, 1996), (Dorigo and Colombetti, 1993, 1995, 1998).

Fuzzy logic has also been used to encode controllers. Possible sensed values and acting values are encoded into predefined fuzzy sets and the rules that relate both things can be evolved. Examples: (Cooper, 1995), (Hoffmann and Pfister, 1994), (Vicente Matellán et al, 1998).

Artificial neural networks are the most common way of implementing controllers in evolutionary robotics.

On one hand, they are noise and failure tolerant and, on the other, they can be used as universal function approximators and can be easily integrated with an evolutionary algorithm to obtain a controller from scratch. Many researchers have used ANNs, just to mention some of them: (Beer and Gallagher, 1992), (Cliff et al, 1992), (Floreano and Mondada, 1998), (Harvey et al, 1993), (Kodjabachian and Meyer, 1995), (Lund and Hallam, 1996), (Nolfi et al, 1994) and (Santos and Duro, 1998).

How to Encode What We are Evolving

When encoding a controller into the chromosome, the most obvious choice, and the most common one, is to make a direct encoding. That is, each controller parameter becomes a gene in the chromosome. For instance, if the controller is an ANN, each synaptic weight as well as the biases and other possible parameters that describe the ANN topology correspond to a gene, (Mataric and Cliff, 1996), (Miglino et al, 1995a). This can lead to very large chromosomes, as the chromosome size grows proportional to the square of the network size (in case of feedforward networks), increasing the dimensionality of the search space and making it more difficult to obtain a solution in reasonable time. Another problem is that the designer has to predefine the full topology (size, number of neurons, etc.) of the ANN, which is, in general, not obvious usually leading to a trial and error procedure. To address this problem, some researchers employ encoding schemes where the chromosome length may vary in time (Cliff et al., 1993b).

Another possibility is to encode elements that, following a set of rules, encode the development of the individual (Guillot and Meyer, 1997), (Angelo Cangelosi et al, 1994), (Kodjabachian and Meyer, 1998). Some authors even simultaneously evolve with this system both the controller and the morphology, but mostly for virtual organisms (Sims, 1994) or very simplified real robots.

Where to Carry Out the Evolution Process

To determine how good an individual is, it is necessary to evaluate this individual in an environment during a given time interval. This **evaluation** has to be performed more than once in order to make the process indepen-

dent from the initial conditions. The more complex the behaviour is the more time that is required to evaluate an individual. The evaluation of the individual is usually the most time consuming phase, by far, in the whole evolutionary process for evolutionary robotics. The evaluation can be carried out in a real environment, in a simulated environment or both.

Evaluation in a real environment has the obvious advantage that the controllers obtained will work without problems in the real robot. But it is much slower than evaluation in simulated environments, it presents the danger of harming the robot and many limitations on the evaluation functions that may be used. These is why researchers that consider evaluation in a real environment mostly use small robots in controlled environments (Dario Floreano and Francesco Mondada, 1995, 1996, 1998).

The alternative is to perform the evaluation in a simulated environment (Beer and Gallagher, 1992), (Cliff et al, 1993a), (Meeden, 1996), (Miglino et al, 1995a, b). This is faster and it permits parallelizing the algorithm and using fitness functions that are impossible in a real environment. Nevertheless, it has the additional problem of how to carry out this simulation in order to obtain controllers that work in the real world. Jakobi (Jakobi 1997) formalized this problem and established the conditions to be taken into account in order to successfully transfer the controllers obtained in simulation to the real robot.

Some researchers choose to perform a simulated evaluation for the different generations of the evolutionary process except in the last generations where a real evaluation is performed to make sure that the controllers work in the real robot. Nevertheless, this approach presents the same problems, although somehow reduced, as the case of evolution in a real environment (Miglino et al, 1995a).

How to Evaluate

Once the previous choices have been made, it is necessary to decide how the **fitness** will be calculated. There are two different perspectives for doing this: a local perspective or a global perspective (Mondada and Floreano, 1995). The first one consists in establishing for each step of the robot life a fitness of its actions in relation to its goal. The final fitness will be the sum of the fitness values corresponding to each step. This strategy presents two main drawbacks. Except in toy problems,

it is very difficult to decide beforehand the fitness of each action towards a final objective. Sometimes the same action may be good or bad depending on what happened before or after in the context. In addition, this approach implies an external determination of goodness as it is the designer who is imposing through these action-fitness pairs how the robot must act.

The global approach, on the other hand, implies defining a fitness criteria based on how good the robot was at achieving its final goal. The designer does not specify how good each action is in order to maximize fitness, and the evolutionary algorithm has a lot more freedom for discovering the best final controller. The main problem here is that there is a lot less knowledge injected in the evolutionary process, and thus the evolution may find loopholes in the problem specification and thus maximize fitness without really achieving the function we seek.

There are two main ways in which global fitness can be obtained: external and internal. By external we mean a fitness assigned by someone or some process outside the robot. An extreme example of external global evaluation of the robot behaviour is presented in (Lund et al, 1998).

The other possible approach is to employ an internal representation of fitness. This is, employ clues in the environment the robot is conscious of and that it can use in order to judge its level of fitness without the help from any external evaluator (apart from the environment itself). A concept often used in order to implement this approach is that of internal energy. The robot has an internal energy level and this energy level increases or decreases according to a set of rules or functions related to robot perceptions. The final fitness of the robot is given by the level of energy at the end of its life.

FUTURE TRENDS

The main problem of the evolutionary approach to robotics is that, although it is easy to obtain simple behaviours, it does not scale well to really complex behaviours without introducing some human knowledge in the system. An obvious solution to this problem is the reduction of evaluation time, which is slowly happening thanks to the increasing computational capabilities. Another way of controlling this problem is to try to obtain a better encoding scheme using development.

Another problem that arises when trying to minimize human intervention is that the evolutionary algorithm can lead to a behaviour that optimizes the defined fitness function but the result does not correspond with the desired behaviour due to an incomplete or inadequate fitness function. This problem must be addressed from a theoretical and formal point of view so that the appropriate fitness functions can be methodologically obtained.

Finally, there is a problem in common with Autonomous Robotics: **benchmarking**. It is not easy to compare different approaches and usually we can only say if a behaviour is satisfactory or not. It is hard to compare it with other similar behaviours or to know if the results would be better by changing something in the approach followed.

CONCLUSION

Evolutionary Robotics has quickly developed from its birth in the beginning of the nineties as the most common way of obtaining behaviours in Behaviour Based Robotics. It has shown that it is the easiest way to automatically obtain controllers for autonomous robots while trying to minimize the human factor, at least when the behaviours are not too complex, due to the fact that it is easy to encode every tool used to implement controllers and obtain a solution by just defining a fitness function. Inside Evolutionary Robotics, simulated evaluation is the preferred way of evaluating how good a candidate solution is and Artificial Neural Networks are the preferred tool to implement controllers due to their noise and failure tolerance and their nature as a universal function approximator. Due to the time required to evaluate individuals and the number of individuals that must be evaluated, the selection of the correct evolutionary algorithm and its parallelization are critical factors.

KEY TERMS

Artificial Neural Network: An interconnected group of artificial neurons, which are elements that use a mathematical model that reproduce, through a great simplification, the behaviour of a real neuron, used for distributed information processing. They are inspired by nature in order to achieve some characteristics presented in the real neural networks, such as error and noise tolerance, generalization capabilities, etc.

Autonomous Robotics: The field of Robotics that tries to obtain controllers for robots so that they are tolerant and may adapt to changes in the environment.

Behaviour Based Robotics: The field of Autonomous Robotics that proposes not to pay attention to the knowledge that leads to behaviours, but just to implement them somehow. It also proposes a direct connection between effectors and actuators for every controller running in the robot, eliminating the typical sensor interpretation, world modelling and planning stages.

Evolutionary Algorithm: Stochastic population based search algorithm inspired on natural evolution. The problem is encoded in an n-dimensional search space where individuals represent candidate solutions. Better individuals have higher reproduction probabilities than worse individuals, thus allowing the fitness of the population to increase through the generations.

Evolutionary Robotics: The field of Autonomous Robotics, usually also considered as a field of Behaviour Based Robotics, that obtains the controllers using some kind of evolutionary algorithm.

Knowledge Based Robotics: The field of Autonomous Robotics that tries to achieve “intelligent” behaviours through the modelling of the environment and a process of planning over that model, that is, modelling the knowledge that generates the behaviour.

MacroEvolutionary Algorithm: Evolutionary algorithm using the concept of species instead of individuals. Thus, low fitness species become extinct and new species appear to fill their place. Its evolution is smoother, slower but less inclined to fall into local optima as compared to other evolutionary algorithms.

INTRODUCTION

Traditionally physical systems have been designed by engineers using complex collections of rules and principles. The design process is top-down in nature and begins with a precise specification. This contrasts very strongly with the mechanisms which have produced the extraordinary diversity and sophistication of living creatures. In this case the “designs” are evolved by a process of natural selection. The design starts as a set of instructions encoded in the DNA whose coding regions are first transcribed into RNA in the cell nucleus and then later translated into proteins in the cell cytoplasm. The DNA carries the instructions for building molecules using sequences of amino acids. Eventually after a number of extraordinarily complex and subtle biochemical reactions an entire living organism is created. The survivability of the organism can be seen as a process of assembling a larger system from a number of component parts and then testing the organism in the environment in which it finds itself (Miller, 2000).

The main target of the **evolvable hardware** is to build a digital circuit using bio inspired methods like genetic algorithms. Here the potential solutions are coded like configuration vectors which command interconnection between logical cells inside the reconfigurable circuit. All configuration vectors represent the genotype and one single configuration vector is the individual with its own characteristics (like chromosome).

The individuals are generated by genetic operators like crossover or mutation. One individual give one solution circuit which is tested in **evaluation** module. The circuit obtained from the individual consist the

phenotype. The circuit behavior is compared with target functions, which we desire to implement. The result is fitness: if the circuit approximates the behavior of the target function, we have a good fitness for the individual which generate the circuit. Then each individual whith its fitness gets into selection module where the future parents in crossover and mutation are decided. Finally we have a circuit solution which implements the target function. We have an evolved synthesis of digital circuit – a method like assemble and test.

This method can be useful because explore the design space beyond the limits imposed by traditional design methods. Two research directions are developed in evolvable hardware. In **extrinsic evolvable hardware** the individuals are obtained from software implementation on computer and phenotype consist in high level abstract circuits like SPICE object files or FPGA configuration files (.bit). The **intrinsic evolution**, on the other hand, supposes that entire evolution process is inside one or more chips (FPGA): the hardware implementation of evolved hardware.

The challenge is to design an intrinsic evolution because can be used for applications like robots control system. But this involves implementation of the software based algorithms in hardware modules.

BACKGROUND

The **dynamic reconfigurable hardware** area and evolvable hardware knows, in the last years, a fast evolution. Ten years ago the digital circuit implementation, with high degree of complexity involve more problems caused specially by technologies limits. The

market was up most by complex programmable gates array or by the low grains field programmable gates array where upon the main problems are the number of Boolean cells available on chip and the delay time. The fast evolution of the technologies increases in our day the performance of programmable circuits. Thus, today is possible to implement a high speed central processing units core which is comparable with the application specific integrated circuit implementations. Therewith the low product costs make that a modern programmable digital circuit can be purchased by end users like students and researchers. Thus an evolution in designing, synthesis and implementation techniques with programmable logic circuits is required. One very attractive direction of research is implementation of hardware bio-inspired systems on programmable logic circuits like neural networks or evolutionary algorithms (e.g. genetic algorithms).

The first research direction in this area is to find solutions for improve the genetic algorithm performance by hardware implementation. Software implementations have the advantage of flexibility and easily configuration. However, the convergence speed is slow because the serial execution of the steps whiles the algorithm run. To increase the speed a parallel implementation of the modules is required (Goldberg, 1995). This is done by hardware implementation on programmable logic circuits. More investigations are done in this area.

The second research direction is to join the concept of assemble-and-test together with an evolutionary algorithm to gradually improve the quality of a design has largely been adopted in the nascent field of **evolvable hardware** where the task is to build an electronic circuit.

Thompson (Thompson, 1999) makes the first research, uses a reconfigurable platform and showed that is possible to evolve a circuit which could discriminate between two square wave signals. He demonstrates that is possible to design digital circuit using evolved algorithm. The evolutionary process had utilized physical proprieties of the underlying silicon substrate to produce an efficient circuit. He argued that artificial evolution can produce design for electronics circuit which lies outside the scope of conventional methods. Koza (Koza, 1997) have pioneered the extrinsic evolution of analogue circuit using SPICE and have automatically generated circuit which are competitive with human designer.

Most workers are content with the extrinsic evolution because the evolutionary algorithm is software – based. But Scott and others achieve different solutions for hardware implementation of evolutionary algorithms. In (Scott, 1997) is design a **hardware genetic algorithm** implemented as pipe line hardware structure in FPGA. His work is a demonstration that full integrated **evolved hardware (intrinsic)** solution can be implemented. To design hardware modules for crossover, selection and mutation are used **combinational networks** such as systolic arrays presented by (Bland2001).

Miller et al. (Miller,2000) give a reference with his work concerned of the evolution of combinational digital circuit to implement arithmetic functions. First he uses the gates networks which evolve in arithmetic circuit but demonstrate that is possible to use evolution of some sub-circuits to achieve more complex circuits.

Another example of extrinsic evolved synthesis is give by Martin's work (Martin 2001). Here the phenotype is give by a hardware description language (HandleC) sequences.

But utilization of genetic algorithm in hardware design is in any more areas. In (Shaaban 2001) is used in integrated circuit design in semiconductor detectors. Yasunaga (Yasunaga 2001) use a hardware synthesis of digital circuit in reconfigurable programmable logic array structure to implement speech recognition system. Recently evolvable synthesis is used for sequential circuit design (Ali 2004) or in digital filters design (Iana2006).

The evolved combinational and sequential synthesis for digital circuits is included as control module for self-contained mobile system to execute more tasks like obstacle avoidance and target hit in (Sharabi2006). In fact the solving of the multi objective (multi task) problems in hardware system by evolutionary is treated by Coello (Collelo 2002) and used in more recent works (Zhao 2006).

The question is: is possible to design digital circuits using an evolutionary algorithm like genetic algorithm (GA)?

To answer of this question, first, the design of a reconfigurable circuit which can be programmed by evolutionary algorithm is required. A solution can be reconfigurable multilayer gates network. Each gate in layer x can be connected or not whit a gate in layer $x+1$.

RECONFIGURABLE GATES NETWORK
AND HARDWARE GENETIC
ALGORITHM

Models Used

This section is dedicated to elaborate models for the two components of the **evolvable hardware microstructures**: **hardware genetic algorithm** and **dynamically reconfigurable circuit**.

In this section is presented first the concept of generic dynamically reconfigurable structures. Here each cell of the network is give by computing units and configurable network unit. To run the algorithm a local computation is perform - arithmetic and logic operation by each cell, and a network computation –each cell can configure the connection with the others cell in the network.

This concept can be extended to multilayer gates network by replace the local computations cell with elementary gates and network connections with switches commands by genetic algorithm (Ionescu2004). In this particularly case dynamically reconfigurable structure became a hardware reconfigurable structure.

In figure 1 is presented the cell of reconfigurable hardware: the generic digital gate.

Each **generic gate** can be configured with a local elementary Boolean function and more switch connections with another gates. Thus, the first coding schema for genetic algorithm is conceived: the individual is a string of connections status and Boolean functions code like Fig1.b.

Each algorithm contains functions which can be executed by central processing unit. To the compute systems with single processor one single function can be executed at time. In hardware structure, each function can be implemented in **combinational network**. There are two main kind of **combinational networks**: the sorting network composes by min/max elementary circuits and the permutation network composes by permutation elementary circuit. In figure 2 are presented the recursive sorting circuit and the recursive permutation circuit.

Figure 1. a) The generic gate – cell of the hardware reconfigurable structure, b) gates network coded as configuration vector

Figure 2. The recursive sorting and permutation circuit used for hardware implementation of the genetic algorithm modules

Design of Hardware Genetic Algorithm, Dynamic Reconfigurable Circuit and Application Description

This section gets into the techniques used for evolvable hardware **microstructures** design. First it presents the design of hardware genetic algorithm by using the models from the preceding section. Each module are designed individually, describe with combinational networks. The hardware genetic algorithm is a circuit which connect all modules in a fully hardware solution. The block diagram of **HGA (hardware genetic algorithm)** is presented in figure below (fig.3).

The main issue of this solution is that the modules can be used in another algorithm and can be interconnected in another way without to be redesigned. Each module can work individual, therefore the structure can process more generation in the same time. On the other side, each module was designed as networks of elementary functions like min/max or permutation. Thus any new change claimed like increasing the size or number of individuals is very easily to made by adding the elementary functions blocks. In the selection module individual (bits string) does, with fitness computed, enter in the left side of the array. Each cell collates fitness values from two inputs x_{in} and y_{in} . The output x_{out} get the individual with the smallest fitness value from the inputs and the output y_{out} individual with

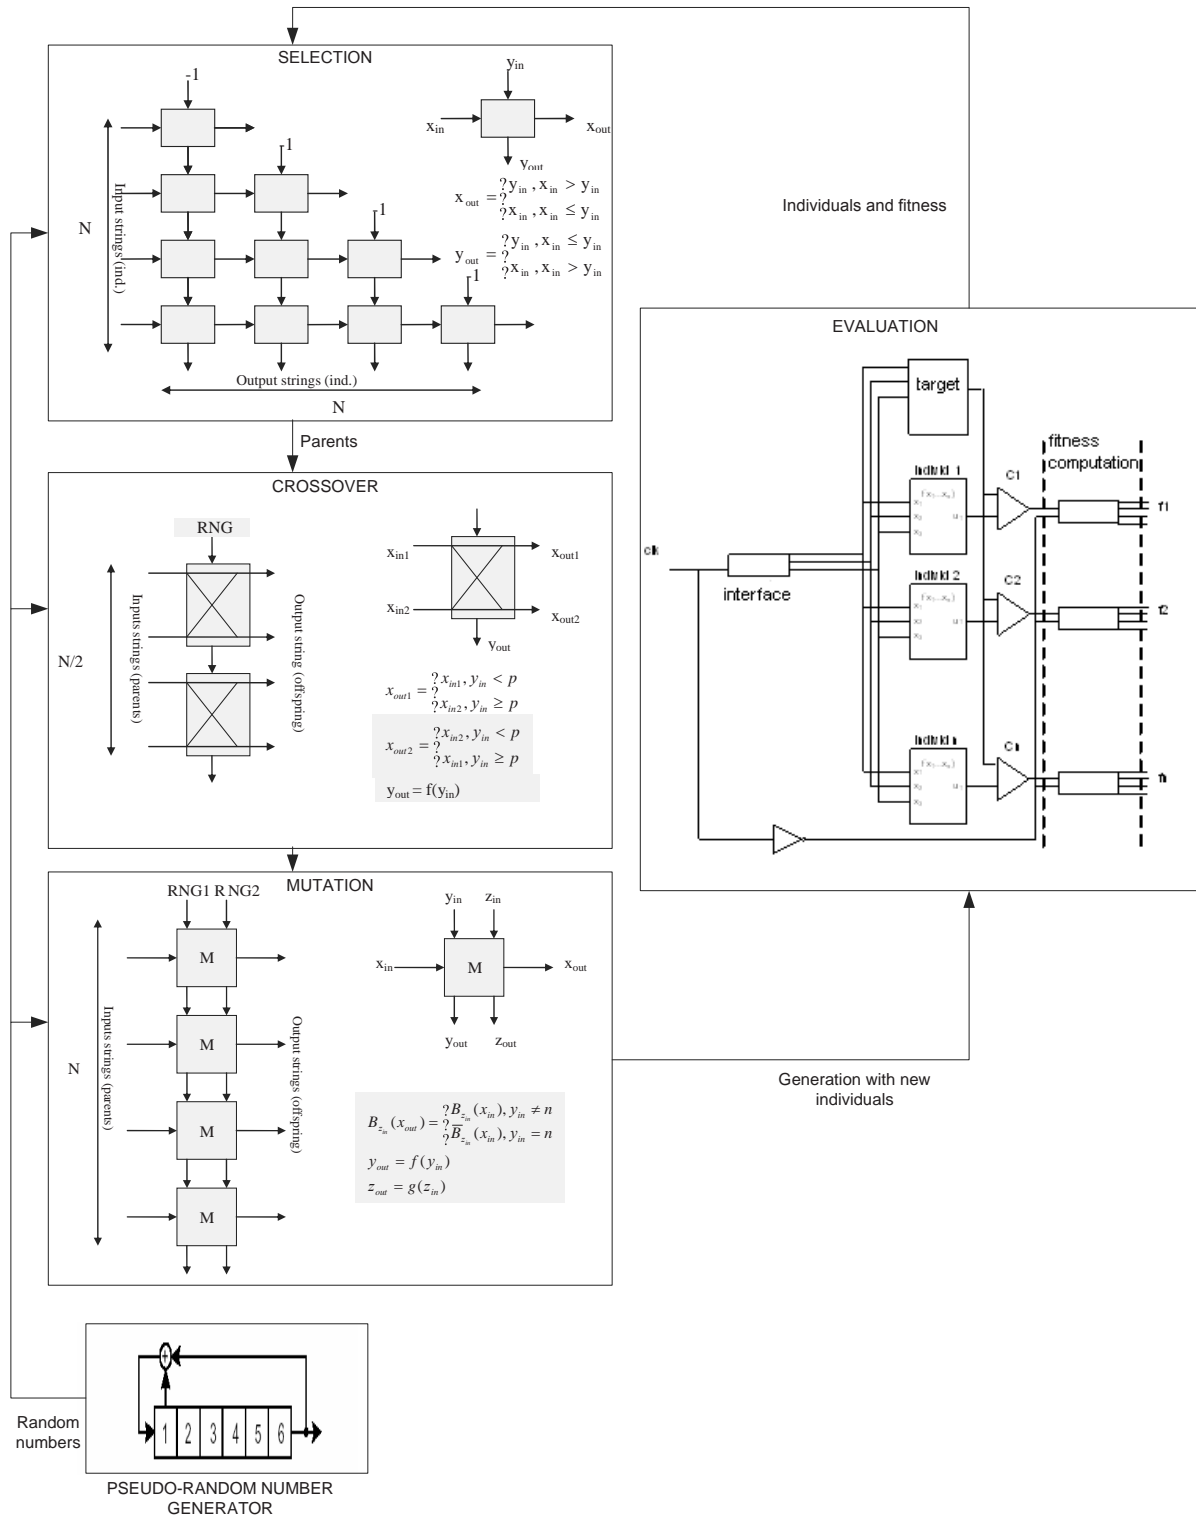

the biggest one. So, the individuals with poor (small value) fitness will cross array on horizontal, from the left to right and individuals with good fitness will cross array from top to bottom on vertical. Finally, we have in the left side outputs with the best fitness.

The same concept are used to crossover circuit. Some individual sorted by selection module enter in crossover module. Operator is applied on a certain number of pair of individuals. Usually, individuals with the best fitness are “parents” for generation 1 of offspring which result from this module.

For mutation module we use one single column of logical structures (mutation cells) too. Array is design with follow restriction: mutation must affect only one single bit from an individual and one single individual from generation (all individuals from one iteration step). Structure can be easily changed if we want another behavior.

Evaluation is done by comparing response of partial solutions provide by each individual and the desirable response. Here is defining a target Boolean function, function which must be implemented in hardware. Another **evaluation** criterion is give by minimization of digital resources used to implement target function. The fitness value is compute consulting both evaluation criterions.

Figure 3. Hardware genetic algorithm

$$f_{total} = 0.9 f_{eval.correct} + 0.1 f_{min.in}$$

Three **dynamic reconfigurable circuits** are designed and tested. All are based on hardware reconfigurable structure presented in figure 1. First schema, min-max terms reconfigurable circuit, use the same principles as programmable logic array. The scheme is composed by three layers: INV layer, AND layer and OR layer. Genetic algorithm command connections between INV layer and AND layer. This reconfigurable circuit has the fast convergence speed and the individuals with the smallest size but explore only traditional space solution and its size grow exponentially with inputs number and linear with outputs number. The second circuit is reconfigurable INV-AND-OR circuit. Like the first circuit, it has three layers: INV layer, AND layer and OR layer. Genetic algorithm configure in this case connections between INV - AND layer and AND - OR layer. This schema reduces the increase of size with number of outputs but remain exponential increase with number of inputs and the size of individuals is bigger than first circuit.

The last reconfigurable circuit is elementary functions reconfigurable circuit (e – reconfigurable). It contains more layers. Each layer contains a number of

generic gates. **Generic gate** can implement a Boolean elementary functions (AND, OR, XOR) and more complex circuits like MUX. This solution increases the size of the individuals and the complexity of the reconfigurable circuit but is almost invariant with number of inputs and outputs.

The last reconfigurable circuit explores the largest solution space, beyond the bounds of traditional design methods.

The **evolvable hardware** is used in three applications. First, the target function is static and algorithm must find hardware solution to implement it. Each individual represent here a potential solution for hardware implementation of target function. Evolution loop is repeated until optimal solution is found. Hardware solution finding here is named evolved hardware. At this time evolution loop is stopped.

In the second application the target function is also static. But here the individual codes only a sub circuit – one **generic gate** or one gates layer. The individuals evolve and the offspring replace the parents in different position and **evaluation** is done to entire circuit until the new solution is better than the old solution. Evolution loop is repeated until optimal solution is found.

This solution is used to design circuit with big number of inputs, outputs and sub circuits.

Figure 4. Reconfigurable elementary functions circuit

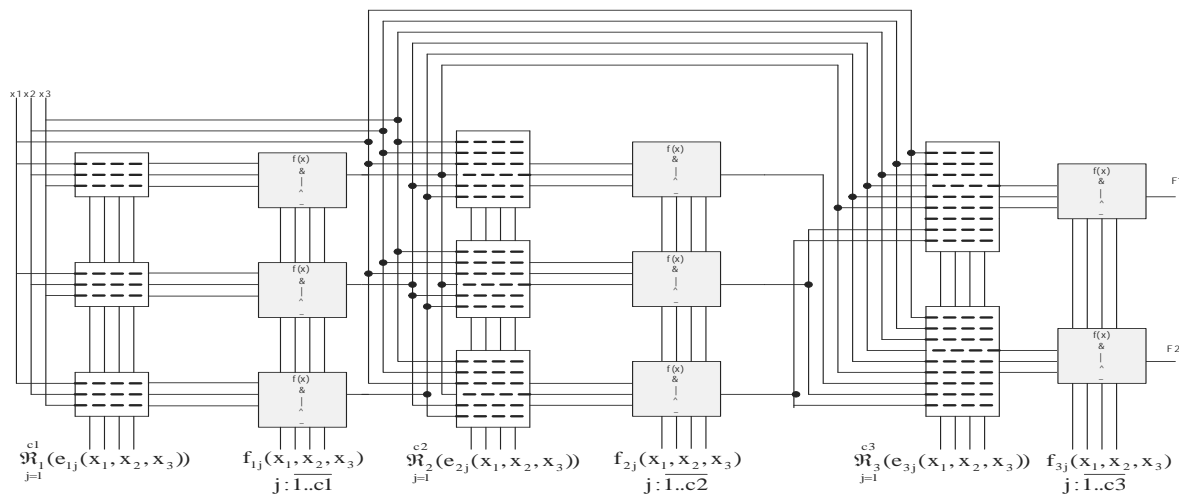

Figure 5. Application schema: Finding optimal solution for target function implementation

The last applications use dynamic target functions. Here each individual represent a complete solution for circuit. Evolution loop here is in two steps. First step is same like in the first application: loop until solution is found. After the solution is found in an individual named main individual the evolution continue for the others individuals. The target of the second step in evolution loop is to obtain different individuals relative to the main individual. When the target function is changed, the evolution loop pass in first step and the individuals, with high degree of dispersion, evolve to new solution.

CONCLUSIONS

In this paper we have presented the concept of the evolvable hardware and show a practical implementation of hardware genetic algorithm and reconfigurable hardware structure.

Hardware genetic algorithm increases the convergence speed to solutions which represent configuration for reconfigurable circuit.

It can be used for evolvable synthesis of digital circuit in intrinsic evolvable hardware. The bit string solutions which are giving by genetic algorithm can be connections configuration for a dynamic reconfigurable hardware circuit.

We present here three architectures of reconfigurable circuits which can be dynamically programmed by same hardware genetic algorithm module. The structure was implemented on Xilinx FPGA Spartan 3.

FUTURE TRENDS

There are more directions of research from this paper. First is design of reconfigurable circuit by using FPGA primitives. The new generation of FPGA (Virtex5) allows dynamically reconfiguration using primitives. In this case the generic gate is replaced by physical cells from FPGA. Another direction is implementation of hybrid neuro-genetic structure. A hardware implementation neural network can be used to store the best solutions from genetic algorithm. This configuration can be used to improve convergence of genetic algorithm. The evolved hardware can be used to design analog circuits. In this case, Boolean reconfigurable circuit can be replacing by analog reconfigurable circuit (like Field Programmable Transistors Area).

KEY TERMS

Evolvable Hardware: Reconfigurable circuit which is programmed by evolved algorithm like GA. To extrinsic evolvable hardware evolved algorithm run to host station outside of the reconfigurable circuit (PC). To intrinsic evolvable hardware evolved algorithm run inside the same system with reconfigurable circuit (even same chip).

Genetic Algorithms (GA): A genetic algorithm (or GA) is a search technique used in computing to find true or approximate solutions to optimization and search problems. Genetic algorithms are categorized as a stochastic local search technique. Genetic algorithms are a particular class of evolutionary algorithms that use techniques inspired by evolutionary biology such as inheritance, mutation, selection, and crossover (also called recombination). Individuals, with coding schema, are initial random values. All individuals are, in the first

step of algorithm evaluated to get the fitness value. In the next step, they are sorted by fitness and selected for genetic operators. The parents are the individuals involved in genetic operators like crossover or mutation. The offspring resulted are evaluated together with parents and the algorithm resume with the first step. The loop is repeated until the solution is find or the number of generation reach the limit given by the programmer.

Genotype: Describe the genetic constitution of an individual, that is the specific allelic makeup of an individual. In evolvable hardware it consist in a vector of configuration bits.

HGA: Hardware genetic algorithm is a hardware implementation of genetic algorithm. Hardware implementation increases the performance of the algorithm by replacing serial software modules with parallel hardware.

Microstructure: Integration of structure in same chip. Evolvable hardware microstructure is an intrinsic evolvable hardware with all modules in same chip.

Phenotype: Describe one of the traits of an individual that is measurable and that is expressed in only a subset of the individuals within that population. In evolvable hardware phenotype consist in the circuit coded by an individual.

Reconfigurable Circuit: Hardware structure consist in logical cell network which allow configuration of the interconnections between cells

Evolving Graphs for ANN Development and Simplification

David Periscal

University of A Coruña, Spain

INTRODUCTION

One of the most successful tools in the Artificial Intelligence (AI) world is Artificial Neural Networks (ANNs). This technique is a powerful tool used in many different environments, with many different purposes, like classification, clustering, signal modelization, or regression (Haykin, 1999). Although they are very easy to use, their creation is not a simple task, because the expert has to do much effort and spend much time on it.

The development of ANNs can be divided into two parts: architecture development and training and validation. The architecture development determines not only the number of neurons of the ANN, but also the type of the connections among those neurons. The training determines the connection weights for such architecture.

The architecture design task is usually performed by means of a manual process, meaning that the expert has to test different architectures to find the one able to achieve the best results. Each architecture trial means training and validating it, which can be a process that needs many computational resources, depending on the complexity of the problem. Therefore, the expert has much participation in the whole ANN development, although techniques for relatively automatic creation of ANNs have been recently developed.

BACKGROUND

ANN development is a research topic that has attracted many researchers from the world of evolutionary algorithms (Nolfi & Parisi D., 2002) (Cantú-Paz & Kamath, 2005). These techniques follow the general strategy of an evolutionary algorithm: an initial population with different types of genotypes encoding also different

parameters – commonly, the connection weights and/or the architecture of the network and/or the learning rules – is randomly created and repeatedly induced to evolve.

The most direct application of EC tools in the ANN world is to perform the evolution of the weights of the connections. This process starts from an ANN with an already determined topology. In this case, the problem to be solved is the training of the connection weights, attempting to minimise the network failure. Most of training algorithms, as backpropagation (BP) algorithm (Rumelhart, Hinton & Williams, 1986), are based on gradient minimisation, which presents several inconveniences. The main of these disadvantages is that, quite frequently, the algorithm gets stuck into a local minimum of the fitness function and it is unable to reach a global minimum. One of the options for overcoming this situation is the use of an evolutionary algorithm, so the training process is done by means of the evolution of the connection weights within the environment defined by both, the network architecture, and the task to be solved. In such cases, the weights can be represented either as the concatenation of binary values or of real numbers on a genetic algorithm (GA) (Greenwood, 1997).

The evolution of architectures consists on the generation of the topological structure, i.e., establishing the connectivity and the transfer function of each neuron. To achieve this goal with an evolutionary algorithm, it is needed to choose how to encode the genotype of a given network for it to be used by the genetic operators.

The most typical approach is called direct encoding. In this technique there is a one-to-one correspondence between each of the genes and a determined part of the network. A binary matrix represents an architecture where every element reveals the presence or absence

of connection between two nodes (Alba, Aldana & Troya, 1993).

In comparison with direct encoding, there are some indirect encoding methods. In these methods, only some characteristics of the architecture are encoded in the chromosome. These methods have several types of representation.

Firstly, the parametric representations represent the network as a group of parameters such as number of hidden layers, number of nodes for each layer, number of connections between two layers, etc (Harp, Samad & Guha, 1989). Another non direct representation type is based on a representation system that uses grammatical rules (Kitano, 1990), shaped as production rules that make a matrix that represents the network.

Another type of encoding is the growing methods. In this case, the genotype contains a group of instructions for building up the network (Nolfi & Parisi, 2002).

All of these methods evolve architectures, either alone (most commonly) or together with the weights. The transfer function for every node of the architecture is supposed to have been previously fixed by a human expert and is the same for all the nodes of the network or, at least, all the nodes of the same layer. Only few methods that also induce the evolution of the transfer function have been developed (Hwang, Choi & Park, 1997).

ANN DEVELOPMENT WITH GENETIC PROGRAMMING

This section very briefly shows an example of how to develop ANNs using an AI tool, Genetic Programming (GP), which performs an evolutionary algorithm, and how it can be applied to Data Mining tasks.

Genetic Programming

GP (Koza, 92) is based on the evolution of a given population. Its working is similar to a GA. In this population, every individual represents a solution for a problem that is intended to be solved. The evolution is achieved by means of the selection of the best individuals – although the worst ones have also a little chance of being selected – and their mutual combination for creating new solutions. After several generations, the population is expected to contain some good solutions for the problem.

The GP encoding for the solutions is tree-shaped, so the user must specify which are the terminals (leaves of the tree) and the functions (nodes capable of having descendants) for being used by the evolutionary algorithm in order to build complex expressions.

The wide application of GP to various environments and its consequent success are due to its capability for being adapted to numerous different problems. Although the main and more direct application is the generation of mathematical expressions (Rivero, Rabuñal, Dorado & Pazos, 2005), GP has been also used in other fields such as filter design (Rabuñal, Dorado, Puertas, Pazos, Santos & Rivero D., 2003), knowledge extraction, image processing (Rivero, Rabuñal, Dorado & Pazos, 2004), etc.

Model Overview

This work will use a graph-based codification to represent ANNs in the genotype. These graphs will not contain any cycles. Due to this type of codification the genetic operators had to be changed in order to be able to use the GP algorithm. The operators were changed in this way:

- The creation algorithm must allow the creation of graphs. This means that, at the moment of the creation of a node's child, this algorithm must allow not only the creation of this node, but also a link to an existing one in the same graph, without making cycles inside the graph.
- The crossover algorithm must allow the crossing of graphs. This algorithm works very similar to the existing one for trees, i.e. a node is chosen on each individual to change the whole subgraph it represents to the other individual. Special care has to be taken with graphs, because before the crossover there may be links from outside this subgraph to any nodes on it. In this case, after the crossover these links are updated and changed to point to random nodes in the new subgraph.
- The mutation algorithm has been changed too, and also works very similar to the GP tree-based mutation algorithm. A node is chosen from the individual and its subgraph is deleted and replaced with a new one. Before the mutation occurs, there may be nodes in the individual pointing to other nodes in the subgraph. These links are updated

Table 1. Summary of the operators to be used in the tree

| Node | Type | Num. Children | Children type |
|------------|--------|---------------|------------------------------|
| ANN | ANN | Num. outputs | NEURON |
| n-Neuron | NEURON | 2*n | n NEURON n REAL (weights) |
| n-Input | NEURON | 0 | - |
| +, -, *, % | REAL | 2 | REAL |
| [-4.4] | REAL | 0 | - |

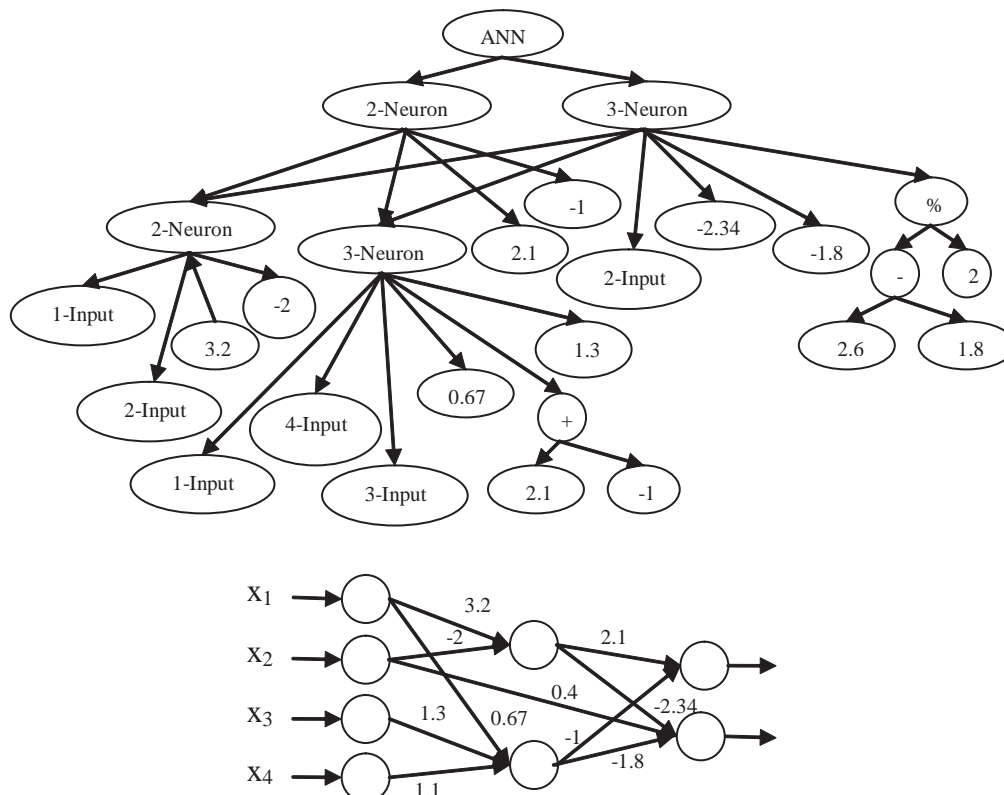

and made to point to random nodes in the new subgraph.

These algorithms must also follow two restrictions in GP: typing and maximum height. The GP typing property (Montana, 1995) means that each node will have a type and will also provide which type will have each of its children. This property provides the ability of developing structures that follow a specific grammar.

In order to be able to use GP to develop any kind of system, it is necessary to specify the set of operators that will be in the tree. With them, the evolutionary system must be able to build correct trees that represent ANNs. An overview of the operators used can be seen on Table 1.

This table shows a summary of the operators that can be used in the tree. This set of terminals and functions are used to build a tree that represents an ANN.

Figure 1. GP graph and its resulting network

Although these sets are not explained in the text, in Fig. 1 can be seen an example of how they can be used to represent an ANN.

These operators are used to build GP trees. These trees have to be evaluated, and, once the tree has been evaluated, the genotype turns into phenotype. In other words, it is converted into an ANN with its weights already set (thus it does not need to be trained) and therefore can be evaluated. The evolutionary process demands the assignation of a fitness value to every genotype. Such value is the result of the evaluation of the network with the pattern set that represents the problem. This result is the Mean Square Error (MSE) of the difference between the network outputs and the desired outputs. Nevertheless, this value has been modified in order to induce the system to generate simple networks. The modification has been made by adding a penalization value multiplied by the number of neurons of the network. In such way, and given that the evolutionary system has been designed in order to minimise an error value, when adding a fitness value, a larger network would have a worse fitness value. Therefore, the existence of simple networks would be preferred as the penalization value that is added is proportional to the number of neurons at the ANN. The calculus of the final fitness will be as follows:

$$fitness = MSE + N * P$$

where N is the number of neurons of the network and P is the penalization value for such number.

Example of Applications

This technique has been used for solving problems of different complexity taken from the UCI (Mertz & Murphy, 2002). All these problems are knowledge-extraction problems from databases where, taking certain features as a basis, it is intended to perform a prediction about another attribute of the database. A small description of the problems to be solved can be seen at Table 2, along with other ANN parameters used later in this work.

All these databases have been normalised between 0 and 1 and divided into two parts, taking the 70% of the data base for training and using the remaining 30% for performing tests.

Results and Comparison with Other Methods

Several experiments have been performed in order to evaluate the system performance. The values taken for the parameters at these experiments were the following:

- Population size: 1000 individuals.
- Crossover rate: 95%.
- Mutation probability: 4%.
- Selection algorithm: 2-individual tournament.
- Graph maximum height: 5.
- Maximum inputs for each neuron: 9.
- Penalization value: 0.00001.

To achieve these values, several experiments had to be done in order to obtain values for these parameters that would return good results to all of the problems. These problems are very different in complexity, so it is expected that these parameters give good results to many different problems.

In order to evaluate its performance, the system presented here has been compared with other ANN generation and training methods.

The method 5x2cv was used by Cantú-Paz and Kamath (1995) for the comparison of different ANN generation and training techniques based on EC tools. This work presents as results the average precisions obtained in the 10 test results generated by this method. Such values are the basis for the comparison of the technique described here with other well known ones, described in detail by Cantú-Paz and Kamath (1995). Such work shows the average times needed to achieve the results. Not having the same processor that was used, the computational effort needed for achieving the results can be estimated. This effort represents the number of times that the pattern file was evaluated. The computational effort for every technique can be measured using the population size, the number of generations, the number of times that the BP algorithm was applied, etc. This calculation varies for every algorithm used. All the techniques that are compared with the work are related to the use of evolutionary algorithms for ANN design. Five iterations of a 5-fold crossed validation test were performed in all these techniques in order to evaluate the accuracy of the networks. These techniques are connectivity matrix, pruning, parameter search and graph-rewriting grammar.

Table 2 shows a summary of the number of neurons used by Cantú-Paz and Kamath (1995) in order to solve the problems that were used with connectivity matrix and pruning techniques. The epoch number of the BP algorithm, when used, is also indicated here.

Table 3 shows the parameter configuration used by these techniques. The execution was stopped after

5 generations with no improvement or after 50 total generations.

The results obtained with these 4 methods are shown in Table 4. Every box of the table indicates 3 different values: precision value obtained by Cantú-Paz and Kamath (1995) (left), computational effort needed for obtaining such value with that technique (below) and

Table 2. Summary of the problems to be solved

| Problem | Description | | | ANN configuration | | | |
|---------------|------------------|---------------------|-------------------|-------------------|--------|---------|-----------|
| | Number of inputs | Number of instances | Number of outputs | Inputs | Hidden | Outputs | BP Epochs |
| Breast Cancer | 9 | 699 | 1 | 9 | 5 | 1 | 20 |
| Iris Flower | 4 | 150 | 3 | 4 | 5 | 3 | 80 |
| Heart Disease | 13 | 303 | 1 | 26 | 5 | 1 | 40 |
| Ionosphere | 34 | 351 | 1 | 34 | 10 | 1 | 40 |

Table 3. Parameters of the techniques used for the comparison

| Parameter | Matrix | Pruning | Parameters | Grammar |
|-----------------------|-----------------------------|-----------------------------|------------|---------|
| Chromosome length (L) | N | N | 36 | 256 |
| Population size | $\lfloor 3\sqrt{L} \rfloor$ | $\lfloor 3\sqrt{L} \rfloor$ | 25 | 64 |
| Crossover points | L/10 | L/10 | 2 | L/10 |
| Mutation rate | 1/L | 1/L | 0.04 | 0.004 |

$$N = (\text{hidden} + \text{output}) * \text{input} + \text{output} * \text{hidden}$$

Table 4. Comparison with other methods

| Problem | Matrix | | Pruning | | Parameters | | Grammar | |
|-----------------|--------|-------|---------|-------|------------|-------|---------|-------|
| Breast Cancer | 96.77 | 96.27 | 96.31 | 95.79 | 96.69 | 96.27 | 96.71 | 96.31 |
| | 92000 | | 4620 | | 100000 | | 300000 | |
| Iris Flower | 92.40 | 95.49 | 92.40 | 81.58 | 91.73 | 95.52 | 92.93 | 95.66 |
| | 320000 | | 4080 | | 400000 | | 1200000 | |
| Heart Cleveland | 76.78 | 81.11 | 89.50 | 78.28 | 65.89 | 81.05 | 72.8 | 80.97 |
| | 304000 | | 7640 | | 200000 | | 600000 | |
| Ionosphere | 87.06 | 88.34 | 83.66 | 82.37 | 85.58 | 87.81 | 88.03 | 88.36 |
| | 464000 | | 11640 | | 200000 | | 600000 | |
| Average | 88.25 | 90.30 | 90.46 | 84.50 | 84.97 | 90.16 | 87.61 | 90.32 |

precision value obtained with the technique described here and related to the previously mentioned computational effort value (right).

Watching this table, it is obvious that the results obtained with the method proposed here are, not only similar to the ones presented by Cantú-Paz and Kamath (1995), but better in most of the cases. The reason of this lies in the fact that these methods need a high computational load since training is necessary for every case of network (individual) evaluation, which therefore turns to be time-consuming. During the work described here, the procedures for design and training are performed simultaneously, and therefore, the times needed for designing as well as for evaluating the network are combined.

FUTURE TRENDS

The future line of works in this area would be the study of the system parameters in order to evaluate their impact on the results from different problems.

Another interesting line consists on the combination of this graph evolution algorithm with a GA that performs an optimization process on the weight values. With this modification, the whole system will have two levels:

1. The graph evolution algorithm explained in this work performs the evolution of the architectures.
2. The GA takes those architectures and optimizes the weights of the connections.

With this architecture, the evolution of ANNs can be seen as a lamarckian strategy.

CONCLUSION

This work describes a technique in which an evolutionary algorithm is used to automatically develop ANNs. This evolutionary algorithm performs graph evolution, and it is based on the GP algorithm, although it had to be modified in order to make it operate with graphs instead of trees.

Results show that the networks returned by this algorithm give, in most of the cases, an error lower than

the error given by the rest of the ANN development systems used for the comparison. Only one technique (pruning) performs better than the one described here. However, that technique still needs some work from the expert, to do the design of the initial network.

Most of the techniques used for the ANN development are quite costly, due in some cases to the combination of training with architecture evolution. The technique described here is able to achieve good results with a low computational cost and besides, the added advantage is that, not only the architecture and the connectivity of the network are evolved, but also the network itself undergoes an optimization process.

ACKNOWLEDGMENT

The development of the experiments described in this work, has been performed with equipments belonging to the Super Computation Center of Galicia (CESGA).

KEY TERMS

Artificial Neural Networks: Interconnected set of many simple processing units, commonly called neurons, that use a mathematical model, that represents an input/output relation,

Back-Propagation Algorithm: Supervised learning technique used by ANNs, that iteratively modifies the weights of the connections of the network so the error given by the network after the comparison of the outputs with the desired one decreases.

Evolutionary Computation: Set of Artificial Intelligence techniques used in optimization problems, which are inspired in biologic mechanisms such as natural evolution.

Genetic Programming: Machine learning technique that uses an evolutionary algorithm in order to optimise the population of computer programs according to a fitness function which determines the capability of a program for performing a given task.

Genotype: The representation of an individual on an entire collection of genes which the crossover and mutation operators are applied to.

Phenotype: Expression of the properties coded by the individual's genotype.

Population: Pool of individuals exhibiting equal or similar genome structures, which allows the application of genetic operators.

Search Space: Set of all possible situations of the problem that we want to solve could ever be in.

Facial Expression Recognition for HCI Applications

Fadi Dornaika

Institut Géographique National, France

Bogdan Raducanu

Computer Vision Center, Spain

INTRODUCTION

Facial expression plays an important role in cognition of human emotions (Fasel, 2003 & Yeasin, 2006). The recognition of facial expressions in **image sequences** with significant head movement is a challenging problem. It is required by many applications such as human-computer interaction and computer graphics animation (Cañamero, 2005 & Picard, 2001). To classify expressions in still images many techniques have been proposed such as Neural Nets (Tian, 2001), Gabor wavelets (Bartlett, 2004), and active appearance models (Sung, 2006). Recently, more attention has been given to modeling facial deformation in dynamic scenarios. Still image classifiers use feature vectors related to a single frame to perform classification. **Temporal classifiers** try to capture the temporal pattern in the sequence of feature vectors related to each frame such as the Hidden Markov Model based methods (Cohen, 2003, Black, 1997 & Rabiner, 1989) and Dynamic Bayesian Networks (Zhang, 2005). The main contributions of the paper are as follows. First, we propose an efficient recognition scheme based on the detection of **keyframes** in videos where the recognition is performed using a temporal classifier. Second, we use the proposed method for extending the human-machine interaction functionality of a robot whose response is generated according to the user's recognized facial expression.

Our proposed approach has several advantages. First, unlike most expression recognition systems that require a frontal view of the face, our system is view- and texture-independent. Second, its learning phase is simple compared to other techniques (e.g., the Hidden Markov Models and Active Appearance Models), that is, we only need to fit second-order Auto-Regressive models to sequences of facial actions. As a result, even when the imaging conditions change the learned Auto-Regressive models need not to be recomputed.

The rest of the paper is organized as follows. Section 2 summarizes our developed appearance-based 3D **face tracker** that we use to track the 3D **head pose** as well as the **facial actions**. Section 3 describes the proposed facial expression recognition based on the detection of keyframes. Section 4 provides some experimental results. Section 5 describes the proposed human-machine interaction application that is based on the developed facial expression recognition scheme.

SIMULTANEOUS HEAD AND FACIAL ACTION TRACKING

In our study, we use the *Candide 3D face model* (Ahlberg, 2001). This 3D deformable wireframe model is given by the 3D coordinates of n vertices. Thus, the 3D shape can be fully described by the $3n$ -vector \mathbf{g} - the concatenation of the 3D coordinates of all vertices. The vector \mathbf{g} can be written as:

$$\mathbf{g} = \mathbf{g}_s + A\boldsymbol{\tau}_a \quad (1)$$

where \mathbf{g}_s is the static shape of the model, $\boldsymbol{\tau}_a$ is the facial action vector, and the columns of A are the Animation Units. In this study, we use six modes for the facial Animation Units (AUs) matrix A , that is, the dimension of $\boldsymbol{\tau}_a$ is 6. These modes are all included in the *Candide* model package. We have chosen the six following AUs: lower lip depressor, lip stretcher, lip corner depressor, upper lip raiser, eyebrow lowerer and outer eyebrow raiser. A cornerstone problem in **facial expression** recognition is the ability to track the local **facial actions**/deformations. In our work, we track the head and facial actions using our **face tracker** (Dornaika & Davoine, 2006). This appearance-based tracker simultaneously computes the 3D **head pose** and the **facial actions** $\boldsymbol{\tau}_a$ by minimizing a distance between

the incoming warped frame and the current appearance of the face. Since the **facial actions**, encoded by the vector τ_a , are highly correlated to the facial expressions, their time series representation can be utilized for inferring the facial expression in videos. This will be explained in the sequel.

EFFICIENT FACIAL EXPRESSION DETECTION AND RECOGNITION

In (Dornaika & Raducanu, 2006), we have proposed a **facial expression** recognition method that is based on the time-series representation of the tracked facial actions τ_a . An analysis-synthesis scheme based on learned auto-regressive models was proposed. In this paper, we introduce a process able to detect **keyframes**

in videos. Once a keyframe is detected, the temporal recognition scheme described in (Dornaika & Raducanu, 2006) will be invoked on the detected keyframe. The proposed scheme has two advantages. First, the CPU time corresponding to the recognition part will be considerably reduced since only few keyframes are considered. Second, since a **keyframe** and its neighbor frames are characterizing the expression, the discrimination performance of the recognition scheme will be boosted. In our case, the keyframes are defined by the frames where the **facial actions** change abruptly. Thus, a keyframe can be detected by looking for a local positive maximum in the temporal derivatives of the facial actions. To this end, two entities will be computed from the sequence of facial actions τ_a that arrive in a sequential fashion: (i) the L_1 norm $\|\tau_a\|_1$, and (ii) the temporal derivative given by:

Figure 1. Efficient facial expression detection and recognition based on keyframes

Figure 2. Keyframe detection and recognition applied on a 1600-frame sequence

$$D_t = \frac{\partial \|\tau_a\|_1}{\partial t} = \sum_{i=1}^6 \frac{\partial \tau_{a(i)}}{\partial t} \quad (2)$$

In the above equation, we have used the fact that the facial actions are positive. Let W be the size of a temporal segment defining the temporal granulometry of the system. In other words, the system will detect and recognize at most one expression every W frames. In practice, W belongs to $[0.5s, 1s]$. The whole scheme is depicted in Figure 1.

In this figure, we can see that the system has three levels: the tracking level, the keyframe detection level, and the recognition level. The tracker provides the facial actions for every frame. Whenever the current video segment size reaches W frames, the keyframe detection is invoked to select a keyframe in the current segment if any. A given frame is considered as a **keyframe** if it meets three conditions: (1) the corresponding D_t is a positive local maximum (within the segment), (2) the corresponding norm $\|\tau_a\|_1$ is greater than a predefined threshold, (3) its far from the previous keyframe by at least W frames. Once a keyframe is found in the current segment, the dynamical classifier described in (Dornaika & Raducanu, 2006) will be invoked.

Figure 2 shows the results of applying the proposed detection scheme on a 1600-frame sequence containing 23 played expressions. Some images are shown in Figure 4. The solid curve corresponds to the norm $\|\tau_a\|_1$, the dotted curve to the derivative D_t and the vertical bars correspond to the detected keyframes. In this example, the value of W is set to 30 frames. As can be seen, out of 1600 frames only 23 keyframes will be processed by the expression classifier.

EXPERIMENTAL RESULTS

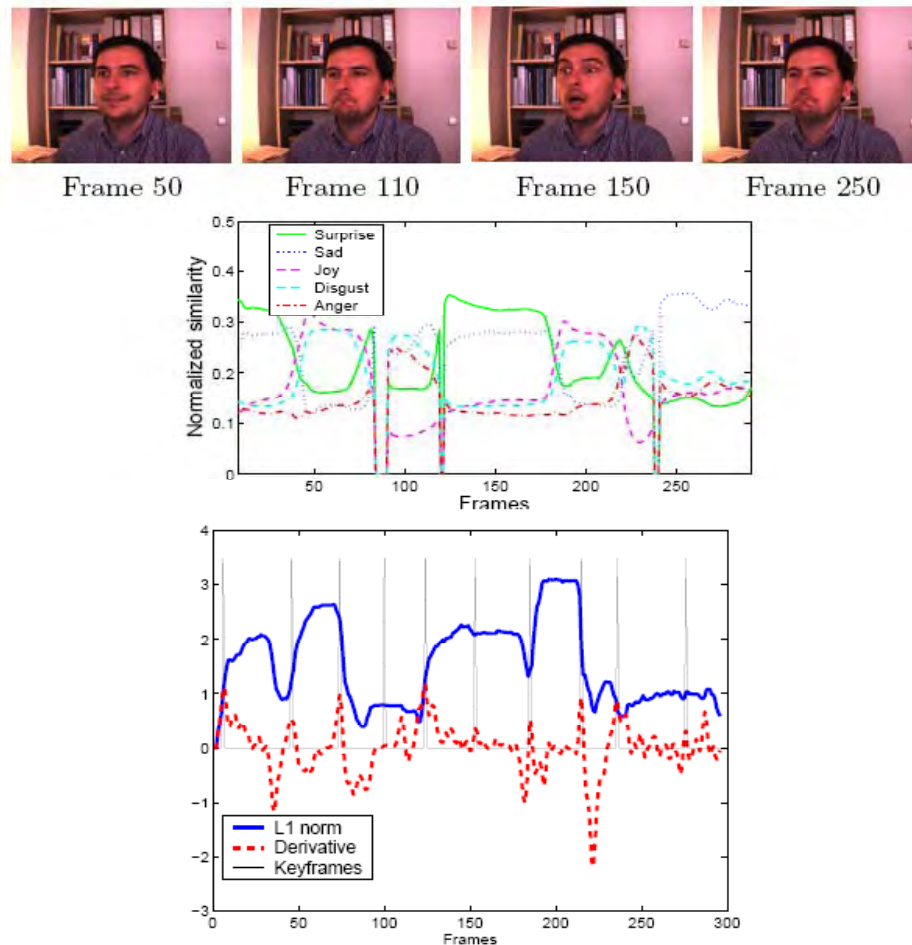

Recognition results: We used a 300-frame video sequence. For this sequence, we asked a subject to display several expressions arbitrarily (see Figure 3). The middle of this figure shows the normalized similarities associated with each universal expression where the recognition is performed for every frame in the sequence. As can be seen, the **temporal classifier** (Dornaika & Raducanu, 2006) has correctly detected the presence of the surprise, joy, and sadness expressions. Note that the mixture of expressions at transition is normal since the recognition is performed in a frame-wise manner. The lower part of this figure shows the results of applying the proposed keyframe detection scheme. On a 3.2 GHz PC, a non-optimized C code of the developed approach carries out the tracking and recognition in about 60 ms.

Performance study: In order to quantify the recognition rate, we have used 35 test videos retrieved from the CMU database. Table 1 shows the confusion matrix associated with the 35 test videos featuring 7 persons. As can be seen, although the recognition rate was good (80%), it is not equal to 100%. This can be explained by the fact that the expression dynamics are highly subject-dependent. Recall that the used auto-regressive models are built using data associated with one subject. Notice that the human ‘ceiling’ in correctly classifying facial expressions into the six basic emotions has been established at 91.7%.

Table 1. Confusion matrix for the facial expression classifier associated with 35 test videos (CMU data). The model is built using one unseen person

| | Surprise (7) | Sadness (7) | Joy (7) | Disgust (7) | Anger (7) |
|----------|--------------|-------------|---------|-------------|-----------|
| Surprise | 7 | 0 | 0 | 0 | 0 |
| Sadness | 0 | 7 | 0 | 5 | 0 |
| Joy | 0 | 0 | 7 | 0 | 0 |
| Disgust | 0 | 0 | 0 | 2 | 2 |
| Anger | 0 | 0 | 0 | 0 | 5 |

Figure 3. Top: Four frames (50, 110, 150, and 250) associated with a 300-frame test sequence. Middle: The similarity measure computed for each universal expression and for each non-neutral frame of the sequence-the framewise recognition. Bottom: The recognition based on keyframe detection.

HUMAN-MACHINE INTERACTION

Interpreting non-verbal face gestures is used in a wide range of applications. An intelligent user-interface not only should interpret the face movements but also should interpret the user's emotional state (Breazeal, 2002). Knowing the emotional state of the user makes machines communicate and interact with humans in a natural way: intelligent entertaining systems for kids, interactive computers, intelligent sensors, social robots,

to mention a few. In the sequel, we will show how our proposed technique lends itself nicely to such applications. Without loss of generality, we use the AIBO robot which has the advantage of being especially designed for Human Computer Interaction. The input to the system is a video stream capturing the user's face.

The AIBO robot: AIBO is a biologically-inspired robot and is able to show its emotions through an array of LEDs situated in the frontal part of the head. In addition to the LEDs' configuration, the robot response

Figure 4. Top: Some detected keyframes associated with the 1600-frame video. Middle: The recognized expression. Bottom: The corresponding robot's response.

contains some small head and body movements. From its concept design, AIBO's affective states are triggered by the Emotion Generator engine. This occurs as a response to its internal state representation, captured through multi-modal interaction (vision, audio and touch). For instance, it can display the 'happiness' feeling when it detects a face (through the vision system) or it hears a voice. But it does not possess a built-in system for vision-based automatic facial-expression recognition. For this reason, with the scheme proposed in this paper (see Section 3), we created an application for AIBO whose purpose is to enable it with this capability.

This application is a very simple one, in which the robot is just imitating the expression of a human subject. Usually, the response of the robot occurs slightly after the apex of the human expression. The results of this application were recorded in a 2 minute video which can be downloaded from the following address: <http://www.cvc.uab.es/~bogdan/AIBO-emotions.avi>. In order to be able to display simultaneously in the video the correspondence between subject's and robot's expressions, we put them side by side.

Figure 4 illustrates five detected keyframes from the 1600 frame video depicted in Figure 2. These are shown in correspondence with the robot's response. The middle row shows the recognized expression. The bottom row shows a snapshot of the robot head when it interacts with the detected and recognized expression.

CONCLUSION

This paper described a view- and texture-independent approach to facial expression analysis and recognition. The paper presented two contributions. First, we proposed an efficient facial expression recognition scheme based on the detection of keyframes in videos. Second, we applied the proposed method in a Human Computer Interaction scenario, in which an AIBO robot is mirroring the user's recognized facial expression.

KEY TERMS

3D Deformable Model: A model which is able to modify its shape while being acted upon by an external influence. In consequence, the relative position of any point on a deformable body can change.

Active Appearance Models (AAM): Computer Vision algorithm for matching a statistical model of object shape and appearance to a new image. The approach is widely used for matching and tracking faces.

AIBO: One of several types of robotic pets designed and manufactured by Sony. Able to walk, “see” its environment via camera, and recognize spoken commands, they are considered to be autonomous robots, since they are able to learn and mature based on external stimuli from their owner or environment, or from other AIBOs.

Autoregressive Models: Group of linear prediction formulas that attempt to predict the output of a system based on the previous outputs and inputs.

Facial Expression Recognition System: Computer-driven application for automatically identifying person’s facial expression from a digital still or video image. It does that by comparing selected facial features in the live image and a facial database.

Hidden Markov Model (HMM): Statistical model in which the system being modeled is assumed to be

a Markov process with unknown parameters, and the challenge is to determine the hidden parameters from the observable parameters. The extracted model parameters can then be used to perform further analysis, for example for pattern recognition applications.

Human–Computer Interaction (HCI): The study of interaction between people (users) and computers. It is an interdisciplinary subject, relating computer science with many other fields of study and research (Artificial Intelligence, Psychology, Computer Graphics, Design).

Social Robot: An autonomous robot that interacts and communicates with humans by following the social rules attached to its role. This definition implies that a social robot has a physical embodiment. A consequence of the previous statements is that a robot that only interacts and communicates with other robots would not be considered to be a social robot.

Wireframe Model: The representation of all surfaces of a three-dimensional object in outline form.

Feature Selection

INTRODUCTION

Many scientific disciplines use modelling and simulation processes and techniques in order to implement non-linear mapping between the input and the output variables for a given system under study. Any variable that helps to solve the problem may be considered as input. Ideally, any classifier or regressor should be able to detect important features and discard irrelevant features, and consequently, a pre-processing step to reduce dimensionality should not be necessary. Nonetheless, in many cases, reducing the dimensionality of a problem has certain advantages (Alpaydin, 2004; Guyon & Elisseeff, 2003), as follows:

- Performance improvement. The complexity of most learning algorithms depends on the number of samples and features (curse of dimensionality). By reducing the number of features, dimensionality is also decreased, and this may save on computational resources—such as memory and time—and shorten training and testing times.
- Data compression. There is no need to retrieve and store a feature that is not required.
- Data comprehension. Dimensionality reduction facilitates the comprehension and visualisation of data.
- Simplicity. Simpler models tend to be more robust when small datasets are used.

There are two main methods for reducing dimensionality: feature extraction and feature selection. In this chapter we propose a review of different feature selection (FS) algorithms, including its main approaches: filter, wrapper and hybrid – a filter/wrapper combination.

BACKGROUND

Feature extraction and feature selection are the main methods for reducing dimensionality. In feature extraction, the aim is to find a new set of r dimensions that are a combination of the n original ones. The best known and most widely used unsupervised feature extraction method is principal component analysis (*PCA*); commonly used as supervised methods are linear discriminant analysis (*LDA*) and partial least squares (*PLS*).

In feature selection, a subset of r relevant features is selected from a set n , whose remaining features will be ignored. As for the evaluation function used, FS approaches can be mainly classified as filter or wrapper models (Kohavi & John, 1997). Filter models rely on the general characteristics of the training data to select features, whereas wrapper models require a predetermined learning algorithm to identify the features to be selected. Wrapper models tend to give better results, but when the number of features is large, filter models are usually chosen because of their computational efficiency. In order to combine the advantages of both models, hybrid algorithms have recently been proposed (Guyon et al., 2006).

FEATURE SELECTION

The advantages described in the Introduction section denote the importance of dimensionality reduction. Feature selection is also useful when the following assumptions are made:

- There are inputs that are not required to obtain the output.
- There is a high correlation between some of the input features.

A feature selection algorithm (FSA) looks for an optimal set of features, and consequently, a paradigm that describes the FSA is heuristic search. Since each state of the search space is a subset of features, FSA can be characterised in terms of the following four properties (Blum & Langley, 1997):

- The initial state. This can be the empty set of features, the whole set or any random state.
- The search strategy. Although an exhaustive search leads to an optimal set of features, the associated computational and time costs are high when the number of features is high. Consequently, different search strategies are used so as to identify a good set of features within a reasonable time.
- The evaluation function used to determine the quality of each set of features. The goodness of a feature subset is dependent on measures. According to the literature, the following measures have been employed: information measures, distance measures, dependence measures, consistency measures, and accuracy measures.
- The stop criterion. An end point needs to be established; for example, the process should finish if the evaluation function has not improved after a new feature has been added/removed.

In terms of search method complexity, there are three main sub-groups (Salapa et al., 2007):

- Exponential strategies involving an exhaustive search of all feasible solutions. Exhaustive search guarantees identification of an optimal feature subset but has a high computational cost. Examples are the branch and bound algorithms.
- Sequential strategies based on a local search for solutions defined by the current solution state. Sequential search does not guarantee an optimal result, since the optimal solution could be in a region of the search space that is not searched. However, compared with exponential searching, sequential strategies have a considerably reduced computational cost. The best known strategies are sequential forward selection and sequential backward selection (SFS and SBS, respectively). SFS starts with an empty set of features and adds features one by one, while SBS begins with a full set and removes features one by one. Features are added or removed on the basis of improvements

in the evaluation function. These approaches do not consider interactions between features, i.e., a feature may not reduce error by itself, but improvement may be achieved by the feature's link to another feature. Floating search (Pudil et al., 1994) solves this problem partially, in that the number of features included and/or removed at each stage is not fixed. Another approach (Sánchez et al., 2006) uses sensitivity indices (the importance of each feature is given in terms of the variance) to guide a backward elimination process, with several features discarded in one step.

- Random algorithms that employ randomness to avoid local optimal solutions and enable temporary transition to other states with poorer solutions. Examples are simulated annealing and genetic algorithms.

The most popular FSA classification, which refers to the evaluation function, considers the three (Blum & Langley, 1997) or last two (Kohavi & John, 1997) groups, as follows:

- Embedded methods. The induction algorithm is simultaneously an FSA. Examples of this method are decision trees, such as classification and regression trees (CART), and artificial neural networks (ANN).
- Filter methods. Selection is carried out as a pre-processing step with no induction algorithm (Figure 1). The general characteristics of the training data are used to select features (for example, distances between classes or statistical dependencies). This model is faster than the wrapper approach (described below) and results in a better generalisation because it acts independently of the induction algorithm. However, it tends to select subsets with a high number of features (even all the features) and so a threshold is required to choose a subset.
- Wrapper methods. Wrapper models use the induction algorithm to evaluate each subset of features, i.e., the induction algorithm is part of the evaluation function in the wrapper model, which means this model is more precise than the filter model. It also takes account of techniques, such as cross-validation, that avoid over-fitting. However, wrapper models are very time consuming, which

Figure 1. Filter algorithm

restricts application with some datasets. Moreover, although they may obtain good results with the inherent induction algorithm, they may perform poorly with an alternative algorithm.

Hybrid methods that combine filter and wrapper methods have recently been attracting a great deal of attention in the FS literature (Liu & Motoda, 1998; Guyon et al., 2006). Although the following sections of this chapter are mainly devoted to filter and wrapper methods, a brief review of the most recent hybrid methods is also included.

Filter Methods

A number of representative filter algorithms are described in the literature, such as χ^2 -Statistic, information gain, or correlation based feature selection (CFS). For the sake of completeness, we will refer to two classical algorithms (FOCUS and RELIEF) and will describe very recently developed filter methods (FCBF and INTERACT). An exhaustive discussion of filter methods is provided in Guyon et al. (2006)—including of methods such as Random Forests (RF), an ensemble of tree classifiers.

FOCUS

In FOCUS (Almuallim & Dietterich, 1991) all feature subsets of increasing size are evaluated until a suitable subset is encountered. Feature subset q is said to be suitable if there is no pair of examples that have different class values and the same values for all the features in q . The successor of this algorithm is FOCUS_2 (Almuallim & Dietterich, 1992), which prunes the search space, thereby evaluating only promising subsets. FOCUS_2 is therefore much faster than FO-

CUS. However, using both algorithms in domains with a large number of features may be computationally unfeasible. Consequently, search heuristics are used in different versions of the algorithm, resulting in good but not necessarily optimal solutions.

RELIEF

The RELIEF algorithm (Kira & Rendell, 1992) estimates the quality of attributes according to how well their values distinguish between instances that are near to each other. For this purpose, given a randomly selected instance, $\mathbf{x}_s = \{x_{1s}, x_{2s}, \dots, x_{ns}\}$, RELIEF searches for its two nearest neighbours: one from the same class, called *nearest hit* H , and the other from a different class, called *nearest miss* M . It then updates the quality estimate for all the features, depending on the values for \mathbf{x}_s , M , and H . RELIEF can deal with discrete and continuous features but is limited to two-class problems. An extension—ReliefF—not only deals with multiclass problems but is also more robust and capable of dealing with incomplete and noisy data. ReliefF was subsequently adapted for continuous class (regression) problems, resulting in the RReliefF algorithm (Robnik-Sikonja & Kononenko, 2003).

FCBF and INTERACT

The fast correlated-based filter (FCBF) method (Yu & Liu, 2003) is based on symmetrical uncertainty (SU), which is defined as the ratio between the information gain and the entropy of two features, x and y :

$$SU(x, y) = 2 \frac{IG(x/y)}{H(x) + H(y)}.$$

This method was designed for high-dimensionality data and has been shown to be effective in removing both irrelevant and redundant features. However, it fails to take into consideration the interaction between features. The INTERACT algorithm (Zhao & Liu, 2007) uses the same goodness measure, SU, but also includes the consistency contribution (c-contribution). It can thus handle feature interaction, and efficiently selects relevant features.

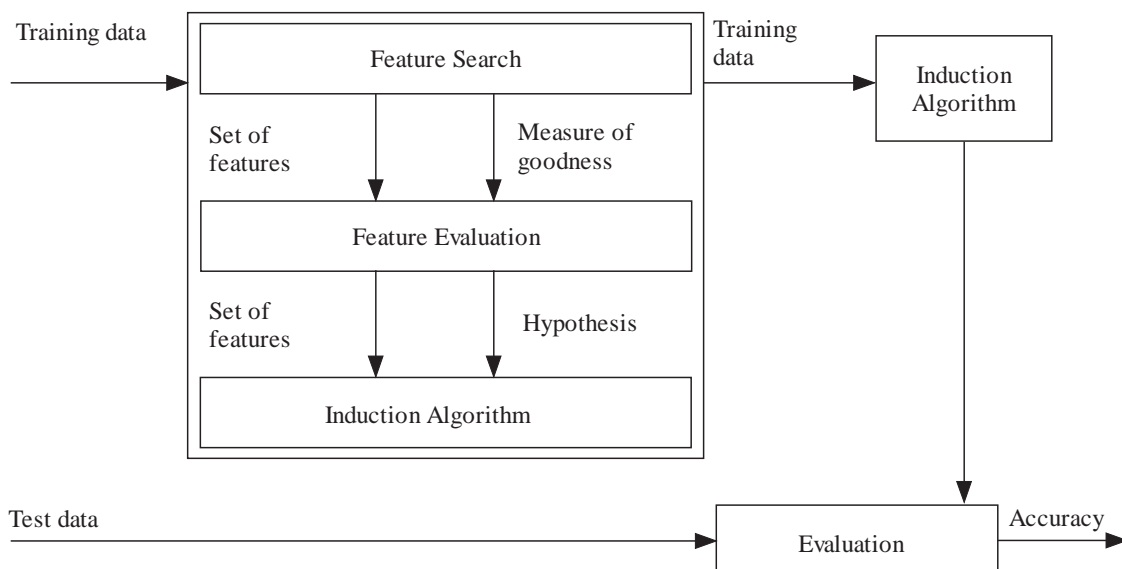

Wrapper Methods

The idea of the wrapper approach is to select a feature subset using a learning algorithm as part of the evaluation function (Figure 2). Instead of using subset sufficiency, entropy or another explicitly defined evaluation function, a kind of “black box” function is used to guide the search. The evaluation function for each candidate feature subset returns an estimate of the quality of the model that is induced by the learning algorithm. This can be rather time consuming, since, for each candidate feature subset evaluated during the search, the target learning algorithm is usually applied several times (e.g., in the case of 10-fold cross validation being used to estimate model quality). Here

we briefly describe several feature subset selection algorithms—developed in machine learning—that are based on the wrapper approach. The literature is vast in this area and so we will just focus on the most representative wrapper models.

An interesting study of the wrapper approach was conducted by Kohavi & John (1997). Besides introducing the notion of strong and weak feature relevance, these authors showed the results achieved by different induction algorithms (ID3, C4.5, and naïve Bayes) in several search methods (best first, hill-climbing, etc.). Aha & Bankert (1995) used a wrapper approach in instance-based learning and proposed a new search strategy that performs beam search using a kind of backward elimination; that is, instead of starting with an empty feature subset, the search randomly selects a fixed number of feature subsets and starts with the best among them. Caruana & Freitag (1994) developed a wrapper feature subset selection method for decision tree induction, proposing bidirectional hill-climbing for the feature space—as more effective than either forward or backward selection. Genetic algorithms have been broadly adopted to perform the search for the best subset of features in a wrapper way (Liu & Motoda, 1998, Huang et al. 2007). The feature selection

Figure 2. Wrapper algorithm

methods using support vector machines (SVMs) have obtained satisfactory results (Weston et al., 2001). SVMs are also combined with other techniques to implement feature selection (different approaches are described in Guyon et al., 2006). Kim et al. (2003) use artificial neural networks (ANNs) for customer prediction and ELSA (Evolutionary Local Selection Algorithm) to search for promising subsets of features.

Hybrid Methods

Whereas the computational cost associated with the wrapper model makes it unfeasible when the number of features is high, when the filter model is used its performance is less than satisfactory. The hybrid model is a good combination of the two approaches that overcomes these problems. Hybrid methods use a filter to generate a ranked list of features. On the basis of the order thus defined, nested subsets of features are generated and computed by a learning machine, i.e. following a wrapper approach (Guyon et al., 2006). The main features of the hybrid model are depicted in Figure 3. One of the first hybrid approaches proposed was that of Yuan et al., 1999. Since then, the hybrid model has focused the attention of the research community and, by now, numerous hybrid models have been developed to solve a variety of problems, such as intrusion detection, text categorisation, etc.

As a combination of filter and wrapper models, there exist a great number of hybrid methods, so it is

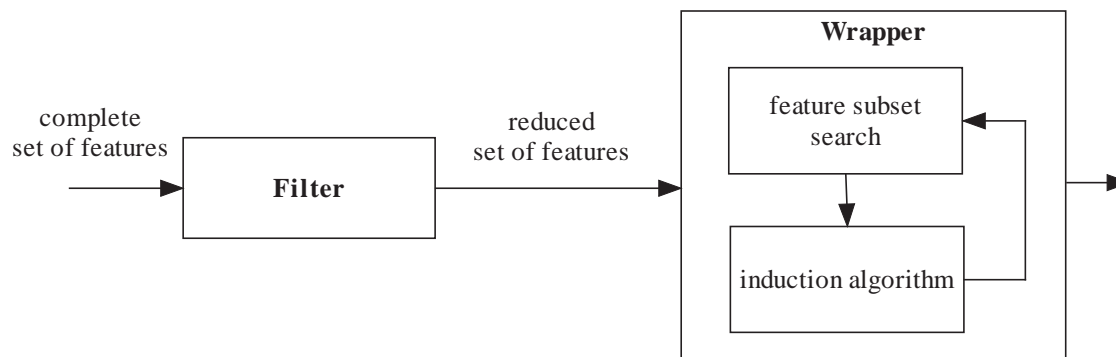

not possible to include all of them and therefore we will refer to some interesting ones. Some hybrid methods involving SVMs are presented in Guyon et al. (2006), chapters 20 and 22. Shazzad & Park (2005) investigate a fast hybrid method –a fusion of Correlation-based Feature Selection, Support Vector Machine and Genetic Algorithm– to determine an optimal feature set. A feature selection model based both on information theory and statistical tests is presented by Sebban & Nock (2002). Zhu et al. (2007) incorporates a filter ranking method in a genetic algorithm to improve classification performance and accelerate the search process.

FUTURE TRENDS

Feature selection is a huge topic that it is impossible to discuss in a short chapter. To pinpoint new topics in this area we refer the reader to the suggestions given by Guyon et al. (2006), summarised as follows:

- Unsupervised variable selection. Although this chapter has focused on supervised feature selection, several authors have attempted to implement feature selection for clustering applications (see, for example, Dy & Brodley, 2004). For supervised learning tasks, one may want to pre-filter a set of the most significant variables with respect to a criterion which does not make use of y to minimise the problem of over-fitting.

Figure 3. Hybrid algorithm

- Selection of examples. Mislabelled examples may induce a choice of wrong variables, so it may be preferable to jointly select both variables and examples.
- System reverse engineering. This chapter focuses on the problem of selecting features useful to build a good predictor. Unravelling the causal dependencies between variables and reverse engineering the system that produced the data is a far more challenging task that is beyond the scope of this chapter (but see, for example, Pearl, 2000).

CONCLUSION

Feature selection for classification and regression is a major research topic in machine learning. It covers many different fields, such as, for example, text categorisation, intrusion detection, and micro-array data. This study reviews key algorithms used for feature selection, including filter, wrapper and hybrid approaches. The review is not exhaustive and is merely designed to give an idea of the state of the art in the field. Most feature selection algorithms lead to significant reductions in the dimensionality of the data without sacrificing the performance of the resulting models. Choosing between approaches depends on the problem in hand. Adopting a filtering approach is computationally acceptable, but the more complex wrapper approach tends to produce greater accuracy in the final result. The filtering approach is very flexible, since any target learning algorithm can be used. It is also faster than the wrapper approach. This latter, on the other hand, is more dependent on the learning algorithm; but the selection process is better. The hybrid approach offers promise in terms of improving results in terms of classification accuracy as well as in terms of the identification of relevant attributes for the analysis.

KEY TERMS

Dimensionality Reduction: The process of reducing the number of features under consideration. The process can be classified in terms of feature selection and feature extraction.

Feature Extraction: A dimensionality reduction method that finds a reduced set of features that are a combination of the original ones.

Feature Selection: A dimensionality reduction method that consists of selecting a subset of relevant features from a complete set while ignoring the remaining features.

Filter Method: A feature selection method that relies on the general characteristics of the training data to select and discard features. Different measures can be employed: distance between classes, entropy, etc.

Hybrid Method: A feature selection method that combines the advantages of wrappers and filters methods to deal with high dimensionality data.

Sequential Backward (Forward) Selection (SBS/SFS): A search method that starts with all the features (an empty set of features) and removes (adds) a single feature at each step with a view to improving -or minimally degrading- the cost function.

Wrapper Method: A feature selection method that uses a learning machine as a “black box” to score subsets of features according to their predictive value.

Feed-Forward Artificial Neural Network Basics

Lluís A. Belanche Muñoz

Universitat Politècnica de Catalunya, Spain

The answer to the theoretical question: “Can a machine be built capable of doing what the brain does?” is yes, provided you specify in a finite and unambiguous way what the brain does.

Warren S. McCulloch

INTRODUCTION

The class of adaptive systems known as Artificial Neural Networks (ANN) was motivated by the amazing parallel processing capabilities of biological brains (especially the human brain). The main driving force was to re-create these abilities by constructing artificial models of the biological neuron. The power of biological neural structures stems from the enormous number of highly interconnected simple units. The simplicity comes from the fact that, once the complex electro-chemical processes are abstracted, the resulting computation turns out to be conceptually very simple.

These artificial neurons have nowadays little in common with their biological counterpart in the ANN paradigm. Rather, they are primarily used as *computational devices*, clearly intended to problem solving: optimization, function approximation, classification, time-series prediction and others. In practice few elements are connected and their connectivity is low. This chapter is focused to supervised feed-forward networks. The field has become so vast that a complete and clear-cut description of all the approaches is an enormous undertaking; we refer the reader to (Fiesler & Beale, 1997) for a comprehensive exposition.

BACKGROUND

Artificial Neural Networks (Bishop, 1995), (Haykin, 1994), (Hertz, Krogh & Palmer, 1991), (Hecht-Nielsen, 1990) are information processing structures without global or shared memory, where each of the computing elements operates only when all its incoming information is available, a kind of data-flow architectures.

Each element is a simple processor with internal and adjustable parameters. The interest in ANN is primarily related to the finding of satisfactory solutions for problems cast as function approximation tasks and for which there is scarce or null knowledge about the process itself, but a (limited) access to examples of response. They have been widely and most fruitfully used in a variety of applications—see (Fiesler & Beale, 1997) for a comprehensive review—especially after the boosting works of (Hopfield, 1982), (Rumelhart, Hinton & Williams, 1986) and (Fukushima, 1980).

The most general form for an ANN is a *labelled directed graph*, where each of the nodes (called *units* or *neurons*) has a certain computing ability and is connected to and from other nodes in the network via labelled edges. The edge label is a real number expressing the strength with which the two involved units are connected. These labels are called *weights*. The *architecture* of a network refers to the number of units, their arrangement and connectivity.

In its basic form, the computation of a unit i is expressed as a function F_i of its input (the *transfer function*), parameterized with its weight vector or local information. The whole system is thus a collection of interconnected elements, and the transfer function performed by a single one (i.e., the *neuron model*) is the most important fixed characteristic of the system.

There are two basic types of neuron models in the literature used in practice. Both express the overall computation of the unit as the composition of two functions, as is classically done since the earlier model proposal of McCulloch & Pitts (1943):

$$F_i(\mathbf{x}) = \{g(h(\mathbf{x}, \mathbf{w}_i)), \mathbf{w}_i \in R^n\}, \quad \mathbf{x} \in R^n \quad (1)$$

where \mathbf{w}_i is the weight vector of neuron i , $h: R^n \times R^n \rightarrow R$ is called the *net input* or *aggregation* function, and $g: R \rightarrow R$ is called the *activation* function. All neuron parameters are included in its weight vector.

The choice $h(\mathbf{x}, \mathbf{w}_i) = \mathbf{x} \cdot \mathbf{w}_i + \theta$, where $\theta \in R$ is an offset term that may be included in the weight vector, leads to one of the most widely used neuron models. When

Figure 1. A classification problem. Left: Separation by spherical RBF units (R-neurons). Right: Separation by straight lines (P-neurons) in the MLP.

neurons of this type are arranged in a feed-forward architecture, the obtained neural network is called MultiLayer Perceptron (MLP) (Rumelhart, Hinton & Williams, 1986). Usually, a smooth non-linear and monotonic function is used as *activation*. Among them, the sigmoids are a preferred choice.

The choice $h(\mathbf{x}, \mathbf{w}_i) = \|\mathbf{x} - \mathbf{w}_i\| / \theta$ (or other distance measure), with $\theta > 0 \in \mathbb{R}$ a smoothing term, plus an activation g with a monotonically decreasing response from the origin, leads to the wide family of localized Radial Basis Function networks (RBF) (Poggio & Girosi, 1989). Localized means that the units give a significant response only in a neighbourhood of their centre \mathbf{w}_i . A Gaussian $g(z) = \exp(-z^2/2)$ is a preferred choice for the activation function.

The previous choices can be extended to take into account extra correlations between input variables. The inner product (containing no cross-product terms) can be generalized to a real quadratic form (an homogeneous polynomial of second degree with real coefficients) or even further to higher degrees, leading to the so-called higher-order units (or Σ - Π units). A higher-order unit of degree k includes all possible cross-products of at most k input variables, each with its own weight. Conversely, basic Euclidean distances can be generalized to completely weighted distance measures, where all the (quadratic) cross-products are included. These full expressions are not commonly used because of the high numbers of free parameters they involve.

These two basic neuron models have traditionally been regarded as completely separated, both from a mathematical and a conceptual point of view. To a certain degree, this is true: the local vs. global approximation approaches to a function that they carry

out make them apparently quite opposite methods (see Fig. 1). Mathematically, under certain conditions, they can be shown to be related (Dorffner, 1995). These conditions (basically, that *both* input and weight vectors are normalized to unit norm) are difficult to fulfil in practice.

A *layer* is defined as a collection of independent units (not connected with one another) sharing the same input, and of the same functional form (same F_i but different \mathbf{w}_i). Multilayer feed-forward networks take the form of directed acyclic graphs obtained by concatenation of a number of layers. All the layers but the last (called the output layer) are labelled as *hidden*. This kind of networks (shown in Fig. 2) compute a parameterized function $F_{\mathbf{w}}(\mathbf{x})$ of their input vector \mathbf{x} by evaluating the layers in order, giving as final outcome the output of the last layer. The vector \mathbf{w} represents the collection of all the weights (free parameters) in the network. For simplicity, we are not considering connections between non-adjacent layers (*skip-layer connections*) and assume otherwise total connectivity. The set of input variables is *not* counted as a layer.

Output neurons take the form of a scalar product (a linear combination), eventually followed by an activation function g . For example, assuming a single output neuron, a one-hidden-layer neural network with h hidden units computes a function $F: \mathbb{R}^n \rightarrow \mathbb{R}$ of the form:

$$F_{\mathbf{w}}(\mathbf{x}) = g\left(\sum_{i=1}^h c_i F_i(\mathbf{x}) - \theta\right) \quad (2)$$

Figure 2. A two-hidden-layer example of ANN, mapping a three-dimensional input space $x=(x_1, x_2, x_3)$ to a two-dimensional output space $(y_1, y_2)=Fw(x)$. The network has four and three units in the first and second hidden layers, respectively, and two output neurons. The vector w represents the collection of all the weights in the network.

where $\theta \in R$ is an offset term (called the *bias* term), $c_i \in R$ and g can be set as desired, including the choice $g(z)=z$. Such a feed-forward network has $\dim(\underline{w})=(n+1)h+h+1$ parameters to be adjusted.

FEED-FORWARD NEURAL NETWORKS

The RBF and MLP networks provide parameterized families of functions suitable to function approximation on multidimensional spaces. A sigmoid neuron puts up an hyperplane that divides its input space in two halves. In other words, the points of equal neuron activation (with fixed weights) are hyperplanes. This behaviour is not caused by the sigmoid, but by the scalar product. The isoactivation contours for an RBF unit (in case of an unweighted Euclidean norm) are hyperspheres. The radially symmetric and centered response is not caused by the activation function (e.g., Gaussian or exponential) but by the norm. In both cases, the activation function acts as a non-linear monotonic distortion of its argument as computed by the aggregation function.

Definition (Isoactivation set). Given a real function $f: R^n \rightarrow (a, b)$, define I_f^α for $\alpha \in (a, b)$ as the set of isoactivation points $I_f^\alpha = \{x \in R^n \mid f(x) = \alpha\}$.

Definition (P-neuron). A neuron model F_i of the form:

$$F_i(x) = \{g(w_i \cdot x + \theta_i), w_i \in R^n, \theta_i \in R\} \quad (3)$$

with g a bounded, non-linear and increasing function for which $\lim_{z \rightarrow \infty} g(z) = g_{max} \in R$ and $\lim_{z \rightarrow -\infty} g(z) = g_{min} \in R$ will be denoted *P*-neuron (from Perceptron). For these neurons, the sets $I_{F_i}^\alpha$ are $(n-1)$ -dimensional hyperplanes for constant values of α , parallel with one another for different α . In practice, the g are usually the well-behaved sigmoids, though other activation functions are sometimes found in the literature (e.g., sinusoid). The latter are not included in the above Definition.

Definition (R-neuron). A neuron model F_i of the form:

$$F_i(x) = \{1/\theta_i g(\|x - w_i\|_q), w_i \in R^n, \theta_i > 0 \in R, q \geq 1 \in R\} \quad (4)$$

where $\|\cdot\|$ is a norm and g is a symmetric function such that $g(\|z\|)$ is monotonic, with a maximum g_{max} at $F_i(w_i)$ and a (possibly asymptotically reached) minimum $g_{min}=0$ will be denoted *R*-neuron (from Radial). For these neurons, the sets $I_{F_i}^\alpha$ are $(n-1)$ -dimensional

Figure 3. The logistic function $l(z)=g^{\log}_{1.5}(z)$ and its first derivative $l'(z)>0$. This function is maximum at the origin, corresponding to a medium activation at $l(0)=0.5$. This point acts as an initial “neutral” value around a quasi-linear slope.

hypersurfaces (centered at w_i) for constant values of α (e.g., hypercubes for $q=1$, hyperspheres for $q=2$) concentric with one another for different α .

The norm used can be any Minkowskian norm of the form:

$$\|z\|_q = \left(\sum_{i=1}^n |z_i|^q \right)^{1/q}, \quad q \geq 1 \in \mathbb{R} \quad (5)$$

In practice, typical choices are $q=2$ and g a Gaussian function.

Due to their widespread use, we present two of the most popular sigmoids, and show how they are tightly related. A *sigmoid* function g can be defined as a monotonically increasing function exhibiting smoothness and asymptotic properties. The two more commonly found representatives are the **logistic**:

$$\frac{1}{1 + \exp(-\beta(z - \theta))} \in (0, 1) \quad (6)$$

and the **hyperbolic tangent**:

$$g^{\tanh}_{\beta}(z) = \frac{\exp(\beta(z - \theta)) - \exp(-\beta(z - \theta))}{\exp(\beta(z - \theta)) + \exp(-\beta(z - \theta))} \in (-1, 1) \quad (7)$$

The offset θ is in practice set to zero, because its function is the same as that of the *bias* term in the aggregation function in (3). These two families of functions can be made exactly the same shape (assuming $\theta=0$) by making the β in (6) be twice the value of the β in (7). For instance, for $\beta=0.5$:

$$g^{\tanh}_{0.5}(z) = g^{\tanh}_1(z/2) = \frac{1 - \exp(-z)}{1 + \exp(-z)} = 2g^{\log}_1(z) - 1 \quad (8)$$

is the bipolar version of $g^{\log}_1(z) = \frac{1}{1 + \exp(-z)}$. These functions are chosen because of their simple analytic behaviour, especially in what concerns differentiability, of great importance for learning algorithms relying in derivative information (Fletcher, 1980). In particular,

$$(g^{\log}_{\beta})'(z) = \beta g^{\log}_{\beta}(z)(1 - g^{\log}_{\beta}(z)) \quad (9)$$

The interest in sigmoid functions also relies in the behaviour of their derivatives. Consider, for example, (6) with $\beta=1.5$ and $\theta=0$, plotted in Fig. (3). The derivative of a sigmoid is always positive. For $\theta=0$, all the functions are centred at $z=0$. In this point, the function has a medium activation, and its derivative is maximum, allowing for maximum weight updates.

Types of Artificial Neural Networks

A fundamental distinction to categorize a neural network relies on the kind of architecture, basically divided in *feed-forward* (for which the graph contains no cycles) and *recurrent* (the rest of situations). A very common feed-forward architecture contains no intra-layer connections and all possible inter-layer connections between adjacent layers.

Definition (Feed-forward neural network: structure). A *bipartitioned graph* is a graph G whose nodes V can be partitioned in two disjoint and proper sets V_1 and V_2 , $V_1 \cup V_2 = V$, in such a way that no pair of nodes in V_1 is joined by an edge, and the same property holds for V_2 . We write then G_{n_1, n_2} , with $n_1 = |V_1|$, $n_2 = |V_2|$. A bipartitioned graph G_{n_1, n_2} is *complete* if every node in V_1 is connected to every node in V_2 . These concepts can be generalized to an arbitrary number of partitions, as follows: A k -partitioned graph G_{n_1, \dots, n_k} is a graph whose nodes V can be partitioned in k disjoint and proper sets V_1, \dots, V_k , such that

$$\bigcup_{i=1}^k V_i = V,$$

in a way that no pair of nodes in V_i is joined by an edge, for all $1 \leq i \leq k$. In these conditions, a feed-forward fully connected neural network with c hidden layers and h_l units per layer l , $1 \leq l \leq c+1$, takes the form of a directed complete $c+1$ -partitioned graph $G_{h_1, \dots, h_{c+1}}$.

Definition (Feed-forward neural network: function). A feed-forward neural network consisting of c hidden layers, denoted $\text{FFNN}(n, c, m)$, is a function $F_{\underline{w}}: R^n \rightarrow R^m$ made up of pieces of the form $\mathbf{y}^{(l)} = (F_1^l(\mathbf{y}^{(l-1)}), \dots, F_{h_l}^l(\mathbf{y}^{(l-1)}))$, representing the output of layer l , for $1 \leq l \leq c+1$. The F^l denote the neuron model of layer l and $h_l \in N^+$ their number, and each neuron F_i^l has its own parameters $\mathbf{w}_i^{(l)}$ as

in Definitions 2 and 3, which are collectively grouped in the *network parameters* \underline{w} . The first output is defined as $\mathbf{y}^{(0)} = \mathbf{x}$. For the last (output) layer, $h_{c+1} = m$ and the F^{c+1}_l , $1 \leq l \leq h_{c+1}$ are P-neurons or *linear units* (obtained by removing the activation function in a P-neuron). The final outcome for $F_{\underline{w}}(\mathbf{x})$ is the value of $\mathbf{y}^{(c+1)}$.

Definition (MLPNN). A MultiLayer Perceptron Neural Network is a FFNN (n, c, m) for which $c \geq 1$ and all the F^l are P-neurons, $1 \leq l \leq c$.

Definition (RBFNN). A Radial Basis Function Neural Network is a FFNN (n, c, m) for which $c=1$ and all the F^c are R-neurons.

LEARNING IN ARTIFICIAL NEURAL NETWORKS

A system can be said to *learn* if its performance on a given task improves with respect to some measure as a result of experience (Rosenblatt, 1962). In ANNs the “experience” is the result of exposure to a training set of data, accompanied with weight modifications. The main problem tackled in *supervised learning* is regression, the approximation of an n -dimensional function $f: X \subset R^n \rightarrow R^m$ by finite superposition (composition and addition) of known parameterized *base functions*, like those in (3) or (4). Their combination gives rise to expressions of the form $F_{\underline{w}}(\mathbf{x})$. The interest is in finding a parameter vector \underline{w}^* of size s such that $F_{\underline{w}^*}(\mathbf{x})$ optimizes a cost functional $L(f, F_{\underline{w}})$ called the *loss*:

$$\underline{w}^* = \underset{\underline{w} \in R^s}{\text{argmin}} L(f, F_{\underline{w}}) \quad (10)$$

The only information available is a finite set D of p noisy samples of f , $D = \{ \langle \mathbf{x}_i, \mathbf{y}_i \rangle, f(\mathbf{x}_i) + \varepsilon_i = \mathbf{y}_i \}$, where $\mathbf{x}_i \in R^n$ is the stimulus, $\mathbf{y}_i \in R^m$ is the target, ε_i is the noise (assumed additive) and $|D| = p$. An estimation of $L(f, F_{\underline{w}})$ can be obtained as $\tilde{L}(D, F_{\underline{w}})$, the *apparent loss*, computed separately for each sample in D ,

$$\tilde{L}(D, F_{\underline{w}}) = \sum_{(\mathbf{x}_i, \mathbf{y}_i) \in D} \lambda(\mathbf{y}_i, F_{\underline{w}}(\mathbf{x}_i)) \quad (11)$$

A common form for λ is an error function, as the squared-error $\lambda(a,b)=(a-b)^2$. This results from the assumption that the noise follows a homocedastic gaussian distribution with zero mean. When using this error, the expression (11) can be viewed as the (squared) Euclidean norm in R^p of the p -dimensional error vector $\mathbf{e}=(e_1,\dots,e_p)$, known as the sum-of-squares error, with $e_i=y_i-F_{\mathbf{w}}(\mathbf{x}_i)$, as:

$$\tilde{L}(D, F_{\mathbf{w}}) = \sum_{(\mathbf{x}_i, y_i) \in D} (y_i - F_{\mathbf{w}}(\mathbf{x}_i))^2 = \mathbf{e} \cdot \mathbf{e} = \|\mathbf{e}\|^2 \quad (12)$$

The usually reported quantity $\|\mathbf{e}\|^2/p$ is called *mean square error* (MSE), and is a measure of the empirical error (as opposed to the unknown *true* error). We shall denote the error function $E(\mathbf{w}) = \tilde{L}(D, F_{\mathbf{w}})$. In a training process, the network builds an internal representation of the target function by finding ways to combine the set of base functions $\{F_i(\mathbf{x})\}_i$. The validity of a solution is mainly determined by an acceptably low and balanced $\tilde{L}(D, F_{\mathbf{w}})$ and $\tilde{L}(D_{out}, F_{\mathbf{w}})$, for any $D_{out} \subset X \setminus D$ (where D_{out} is not used in the learning process) to ensure that f has been correctly estimated from the data. Network models too inflexible or simple or, on the contrary, too flexible or complex will generalize inadequately. This is reflected in the bias-variance tradeoff: the expected loss for finite samples can be decomposed in two opposing terms called *error bias* and *error variance* (Geman, Bienenstock & Doursat, 1992). The expectation for the sum-of-squares error function, averaged over the complete ensemble of data sets D is written as (Bishop, 1995):

$$\begin{aligned} E(\mathbf{w}) &= E_D \{ (F_{\mathbf{w}}(\mathbf{x}) - \langle y/\mathbf{x} \rangle)^2 \} \\ &= (E_D \{ (F_{\mathbf{w}}(\mathbf{x}) - \langle y/\mathbf{x} \rangle)^2 \} + E_D \{ (F_{\mathbf{w}}(\mathbf{x}) - E_D \{ F_{\mathbf{w}}(\mathbf{x}) \})^2 \}) \end{aligned} \quad (13)$$

where E_D is the expectation operator taken over every data set of the same size as D and $\langle y/\mathbf{x} \rangle$ denotes the

conditional average of the target $y=f(\mathbf{x})$ (which expresses the optimal network mapping), given by:

$$\langle y/\mathbf{x} \rangle = \int y p(y/\mathbf{x}) dy$$

The first term in the right hand side of (13) is the (squared) bias and the second is the variance. The bias measures the extent to which the average (over all D) of $F_{\mathbf{w}}(\mathbf{x})$ differs from the desired target function $\langle y/\mathbf{x} \rangle$. The variance measures the sensitivity of $F_{\mathbf{w}}(\mathbf{x})$ to the particular choice of D . Too inflexible or simple models will have a large bias, while too flexible or complex will have a large variance. These are complementary quantities that have to be minimized simultaneously; both can be shown to decrease with increasing availability of larger data sets D .

The expressions in (13) are functions of an input vector \mathbf{x} . The average values for bias and variance can be obtained by weighting with the corresponding density $p(\mathbf{x})$:

$$\begin{aligned} &\int E_D \{ (F_{\mathbf{w}}(\mathbf{x}) - \langle y/\mathbf{x} \rangle)^2 \} p(\mathbf{x}) d\mathbf{x} \\ &= \int (E_D \{ (F_{\mathbf{w}}(\mathbf{x}) - \langle y/\mathbf{x} \rangle)^2 \} p(\mathbf{x}) d\mathbf{x} \\ &+ \int E_D \{ (F_{\mathbf{w}}(\mathbf{x}) - E_D \{ F_{\mathbf{w}}(\mathbf{x}) \})^2 \} p(\mathbf{x}) d\mathbf{x} \end{aligned} \quad (14)$$

Key conditions for acceptable performance on novel data are given by a training set D as large and representative as possible of the underlying distribution, and a set D_{out} of previously unseen data which should not contain examples exceedingly different from those in D . An important consideration is the use of a net with minimal complexity, given by the number of free parameters (the number of components in \mathbf{w}). This requirement can be realized in various ways. In regularization theory, the solution is obtained from a variational principle including the loss and prior smoothness information, defining a *smoothing functional* ϕ such that lower values correspond to smoother functions. A solution of the approximation problem is then given by minimization of the functional (Giroi, Jones & Poggio, 1993):

$$H(F_{\underline{w}}) = \tilde{L}(D, F_{\underline{w}}) + \eta \phi(F_{\underline{w}}) \quad (15)$$

where η is a positive scalar controlling the tradeoff between fitness to the data and smoothness of the solution. A common choice is the second derivative $P(f) = f''$ of which the (squared) Euclidean norm is taken:

$$\phi(F_{\underline{w}}) = \|P(F_{\underline{w}})\|^2 = \int \{F_{\underline{w}}''(t)\}^2 dt \quad (16)$$

CONCLUSION

Artificial Neural Networks are information processing structures evolved as an abstraction of known principles of how the brain might work. The computing elements, called *neurons*, are linked to one another with a certain strength, called *weight*. In their simplest form, each unit computes a *function* of its inputs—which are either the outputs from other units or external signals—influenced by the weights of the links conveying these inputs. The network is said to *learn* when the weights of all the units are adapted to represent the information present in a sample, in an optimal sense given by an error function. The network relies upon the representation capacity of the neuron model as the cornerstone for a good approximation.

KEY TERMS

Architecture: The number of artificial neurons, its arrangement and connectivity.

Artificial Neural Network: Information processing structure without global or shared memory that takes the form of a directed graph where each of the computing elements (“neurons”) is a simple processor with internal and adjustable parameters, that operates only when all its incoming information is available.

Bias-Variance Tradeoff: The mean square error (to be minimized) decomposes in a sum of two non-negative terms, the squared bias and the variance. When an estimator is modified so that one term decreases, the other term will typically increase.

Feed-Forward Artificial Neural Network: Artificial Neural Network whose graph has no cycles.

Learning Algorithm: Method or algorithm by virtue of which an Artificial Neural Network develops a representation of the information present in the learning examples, by modification of the weights.

Neuron Model: The computation of an artificial neuron, expressed as a function of its input and its weight vector and other local information.

Weight: A free parameter of an Artificial Neural Network, that can be modified through the action of a Learning Algorithm to obtain desired responses to input stimuli.

Finding Multiple Solutions with GA in Multimodal Problems

Marcos Gestal

University of A Coruña, Spain

Mari Paz Gómez-Carracedo

University of A Coruña, Spain

INTRODUCTION

Traditionally, the Evolutionary Computation (EC) techniques, and more specifically the Genetic Algorithms (GAs) (Goldberg & Wang, 1989), have proved to be efficient when solving various problems; however, as a possible lack, the GAs tend to provide a unique solution for the problem on which they are applied. Some non global solutions discarded during the search of the best one could be acceptable under certain circumstances. The majority of the problems at the real world involve a search space with one or more global solutions and multiple local solutions; this means that they are multimodal problems (Harik, 1995) and therefore, if it is desired to obtain multiple solutions by using GAs, it would be necessary to modify their classic functioning outline for adapting them correctly to the multimodality of such problems.

MOTIVATION

This chapter tries to establish the basis for the understanding of multimodality where, firstly, the characterisation of the multimodal problems will be attempted. It would be also tried to offer a global view of some of the several approaches proposed for adapting the classic functioning of the GAs to the search of multiple solutions. Lastly, the contributions of the authors will be also showed.

BACKGROUND: CHARACTERIZATION OF MULTIMODAL PROBLEMS

The multimodal problems can be briefly defined as those problems that have multiple global optimums or multiple local optimums.

For this type of problems, it is interesting to obtain the greatest number of solutions due to several reasons; on one hand, when there is not a total knowledge of the

Figure 1. Rastrigin function

problem, the solution obtained might not be the best one as it can not be stated that no better solution could be found at the search space that has not been explored yet. On the other hand, although being certain that the best solution has been achieved, there might be other equally fitted or slightly worst solutions that might be preferred due to different factors (easier application, simpler interpretation, etc.) and therefore considered globally better.

One of the most characteristic multimodal functions used in lab problems are the Rastrigin function (see Fig. 1) which offers an excellent graphical point of view about multimodality means.

Providing multiple optimal (and valid) solutions and not only the unique global solution is crucial in multiple environments. Usually, it is very complex to implement in the practice the best solution represents, so it can offers multiple problems: computational cost too high, complex interpretation,...

In these situations it turns out useful to have a range of valid solutions between which that one could choose that, still not being the best solution to the raised problem, offer a level of acceptable adjustment and be simpler to implement, to understand, ... that the ideal global one.

EVOLUTIONARY TECHNIQUES AND MULTIMODAL PROBLEMS

As it has been mentioned, the application of EC techniques to the resolution of multimodal problems sets out the difficulty that this type of techniques shows since they tend to solely provide the best of the found solutions and to discard possible local optimums that might have been found throughout the search. Quite many modifications have been included in the traditional performance of the GA in order to achieve good results with multimodal problems.

A crucial aspect when obtaining multiple solutions consists on keeping the diversity of the genetic population, distributing as much as possible the genetic individuals throughout the search space.

CLASSICAL APPROACHES

Nitching methods allow GAs to maintain a genetic population of diverse individuals, so it is possible

to locate multiple optimal solutions within a single population.

In order to minimise the impact of homogenisation, or to tend that it may only affect later states of searching phase, several alternatives have been designed, based most of them on heuristics. One of the first alternatives for promoting the diversity was the applications of scaling methods to the population in order to emphasize the differences among the different individuals. Other direct route for avoiding the diversity loss involves focusing on the elimination of duplicate partial high fitness solutions (Bersano, 1997) (Langdon, 1996).

Some other of the approaches tries to solve this problem by means of the dynamic variation of crossover and mutation rates (Ursem, 2002). A higher amount of mutations are done in order to increase the exploration through the search space, when diversity decreases; the mutations decrease and crossovers increase with the aim of improving exploitation in optimal solution search when diversity increases. There are also proposals of new genetic operators or variations of the actual ones. For example some of the crossover algorithms that improve diversity and that should be highlighted are BLX (Blend Crossover) (Eshelman & Schaffer, 1993), SBX (Simulated Binary Crossover) (Deb & Agrawal, 1995), PCX (Parent Centric Crossover) (Deb, Anand & Joshi, 2002), CIXL2 (Confidence Interval Based Crossover using L2 Norm) (Ortiz, Hervás & García, 2005) or UNDX (Unimodal Normally Distributed Crossover) (Ono & Kobayashi, 1999).

Regarding replacement algorithms, schemes that may keep population diversity have been also looked for. An example of this type of schemes is crowding (DeJong, 1975)(Mengshoel & Goldberg, 1999). Here, a newly created individual is compared to a randomly chosen subset of the population and the most closely individual is selected for replacement. Crowding techniques are inspired by Nature where similar members in natural populations compete for limited resources. Likewise, dissimilar individuals tend to occupy different niches and are unlikely to compete for the same resource, so different solutions are provided.

Fitness sharing was firstly implemented by Goldberg & Richardson for being used on multimodal functions (Goldberg & Richardson, 1999). The basic idea involves determining, from the fitness of each solution, the maximum number of individuals that can remain around it, awarding the individuals that exploit unique areas of the domain. The dynamic fitness shar-

ing (Miller & Shaw, 1995) with two components was proposed in order to correct the dispersion of the final distribution of the individuals into niches: the distance function, which measures the overlapping of individuals, and the comparison function, which results “1” if the individuals are identical and values closer to “0” as much different they are.

The clearing method (Petrovski, 1996) is quite different from the previous ones, as the resources are not shared, but assigned to the best individuals, who will be then kept at every niche.

The main inconvenience of the techniques previously described lies in the fact that they add new parameters that should be configured according the process of execution of GA. This process may be disturbed by the interactions among those parameters (Ballester & Carter, 2003).

OWN PROPOSALS

Once detected the existing problems they should be resolved, or at least, minimized. With this goal, the Artificial Neural Network and Adaptive System (RNASA) group have developed two proposals that use EC techniques for this type of problems. Both proposals try to find the final solution but keeping partial solutions within the final population.

The main ideas of the two proposals, together with the problems used for the tests are explained at the following points.

Hybrid Two-Population Genetic Algorithm

Introduction

To force a homogeneous search throughout the search space, the approach proposed here is based on the addition of a new population (genetic pool) to a traditional GA (secondary population). The genetic pool will divide the search space into sub-regions. Every one of the individuals of the genetic pool has its own fenced range for gene variation, so every one of these individuals would represent a specific sub-region within the global search space. On the other hand, the group of individual ranges in which any gene may have its value, is extended over the whole of those possible values that a gene may have. Therefore, this genetic pool would sample the whole of the search space.

It should be borne in mind that a traditional GA performs its search considering only one sub-region (the whole of the search space). Here the search space will be divided into different subregions or intervals according to the number of genetic individuals in the genetic pool.

Since the individuals in the genetic pool have restrictions in their viable gene values, one of these individuals would not be provided a valid solution. So, it is also used another population (the secondary population) in addition to the genetic pool. Here, a classical GA would develop its individuals in an interactive fashion with those individuals of the genetic pool.

Unlike at genetic pool, the genes of individuals of secondary population may adopt values throughout the

Figure 2. Structure of populations of hybrid two-population genetic algorithm

whole of the search space, so it would contribute the solutions, whereas the genetic pool would act as a support, keeping search space homogeneously explored.

The secondary population will provide the solutions (since its individuals are allowed to vary along all the search space range), whereas the genetic pool would act as a support, keeping search space homogeneously explored.

Next, both populations, which are graphically represented in Fig. 2, will be described in detail.

The Genetic Pool

As it has been previously mentioned, every one of the individuals at the genetic pool represents a sub-region of the global search space. Therefore, they should have the same structure or gene sequence than when using a traditional GA. The difference lies in the range of values that these genes might have.

When offering a solution, traditional GA may have any valid value, whereas in the proposed GA, the range of possible values is restricted. Total value range is divided into the same number of parts than individuals in genetic pool, so that a sub-range of values is allotted to each individual. Those values that a given gene may have will remain within its range for the whole of the performance of the proposed GA.

In addition to all that has been said, every individual at the genetic pool will be in control of which are the genes that correspond to the best found solution up to then (meaning whether they belong to the best individual at secondary population). This Boolean value would be used to avoid the modification of those genes that, in some given phase of performance, are the best solution to the problem.

Furthermore, every one of the genes in an individual has an I value associated which indicates the relative increment that would be applied to the gene during a mutation operation based only on increments and solely applied to individuals of the genetic pool. It is obvious that this incremental value should have to be

lower than the maximum range in which gene values may vary. The structure of the individuals at genetic pool is shown at Fig.3.

As these individuals do not represent global solutions to the problem that has to be solved, so their fitness value will not be compulsory. It will reduce the complexity of the algorithm and, of course, it will increase the computational efficiency of the final implementation.

The Secondary Population

The individuals of the secondary population are quite different for the previous. In this case, the genes of the individuals on the secondary population can take any value throughout the whole space of possible solutions. This allows that all individuals on secondary population are able to offer global solutions to the problem. This is not possible in genetic pool because their genes were restricted to different sub-ranges.

The evolution of the individuals at the genetic pool will be carried out by a traditional GA rules. The main difference lies in the operator crossover. In this case a modified crossover will be used. Due to the information is stored in isolated population, now the two parents who will produce the new offspring will not belong to the same population. Hence, the genetic pool and secondary population are combined instead. In this way information of both populations will be merged to produce the most fitted offspring.

The Crossover Operator

As it was pointed before the crossover operator recombines the genetic material of the individuals of both populations. This recombination involves a random individual from secondary population with a representative of the genetic pool.

This representative will represent a potential solution offered by the genetic pool. As a unique individual can not verify this requirement, the representative will

Figure 3. Structure of the genetic pool individuals

Figure 4. Hybrid two-population genetic algorithm: Crossover

be formed by a subset of genes of different individuals on the genetic pool. Gathering information from different partial solutions will allow producing a valid global solution.

Therefore, the value for every gene of the representative will be randomly chosen among all the individuals in the genetic pool. After a value is assigned to all the genes, this new individual represents not a partial, unlike every one of the individuals separately, but a global solution.

Now, the crossover operator will be applied. This crossover function will keep the secondary population diversity, so the offspring will contain values from the genetic pool. Therefore the genetic algorithm would be able to maintain multiple solutions in the same population. The crossover operator does not change the genetic pool because the last one only acts as an engine to keep the diversity

This process is summarized in Fig 4.

The Mutation Operator

Mutation operator increments the value of individual genes in the genetic pool. It introduces new information in the genetic pool, so the representative can use it and finally, by means of the crossover operator, introduce it in secondary population.

It should be noted that the new value will have upper limit, so when it is reached the new gene value will be reset to the lower value.

When generations advance the increment amount is reduced, so the increment applied to the individuals in the genetic pool will take lower values. The different increments between iterations are calculated taking in mind the lower value for a gene (LIM_INF_IND), the

upper value for that gene (LIM_SUP_IND) and the total number of individuals in the genetic pool (IND_POOL) as Fig. 5 summarize. In such way, first generations will explore the search space briefly (a coarse-grain search) and it is intended to do a more exhaustive route through all the values that a given gene may have (a fine-grain search) as the search process advance.

Genetic Algorithm with Division into Species

Another proposed solution is an adaptation of the niching technique. This adaptation consists on the division of the genetic population into different and independent subspecies. In this case the criterion that determines the specie for a specific individual to concrete specie is done according to genotype similarities (similar genotypes will form isolated species). This classical concept has been provided with some improvements in order to, not only decrease the number of iterations needed for obtaining solutions, but also increase the number of solutions kept within the genetic population.

Several iterations of the GA were executed on every species of the genetic population for speeding up the convergence towards the solution that exists near every species. The individuals generated during this execution having a genotype of a different species will be discarded.

The crossover operations between the species are following applied similarly to what happens in biology. It origins, on one hand, the crossovers between similar individuals are preferred (as it was done at the previous step using GAs) and on the other, the crossovers between different species are enabled, although in a lesser rate.

Figure 5. Pseudocode for mutation and Delta initialization

```

IF (not Bi)
  Gi = Gi + li
  IF (Gi > LIM_SUP_GEN)
    Gi = LIM_INF_GEN
    li = li - Delta
  ENDIF
ENDIF
ENDIF

```

$$\text{Delta} = \frac{(\text{LIM_SUP_IND}) - (\text{LIM_INF_IND})}{\text{IND_POOL}}$$

The individuals generated after these crossovers could, either be incorporated to an already existing species or, if they analyse a new area of the search space, create themselves a new species.

Finally, the GA provides as much solutions as species remains actives over the search space.

FUTURE TRENDS

Since there are not any methods that provide the best results in all the possible situations, new approaches would be developed.

New fitness functions would help to locate a great number of valid solutions within the search space. In the described approaches this functions remains constants over the method execution. Another option would be allow dynamical fitness functions that vary along the execution stage. These kind of functions will try to adapt their output with the knowledge extracted from the search space while the crossover and mutation operators explore new arenas.

If different techniques offer acceptable solutions, other interesting approach an interesting point consists on putting together. For example, this hybrid models would integrate statistics methods (with a great mathematical background) with other heuristics.

CONCLUSION

This article shows an overview of the different methods related with evolutionary techniques used to address the problem of multimodality. This chapter showed several approaches to provide, not only a global solution, but multiple solutions to the same problem. It would help

the final user to decide which of them is the most suitable in any particular case.

The final decision will depend on several factors, not only the global error reached for a particular method. Other factors also depend on the economic impact, the difficulty to implement it, the quality of the knowledge provided for their analysis, and so on.

KEY TERMS

Crossover: Genetic operation included in evolutionary techniques used to generate the offspring from current population. There are very different methods to perform crossover, but the general idea resides in merging the genetic information of the parents within the offspring with the aim of produce better solutions as generations advance.

Evolutionary Technique: Technique which tries to provide solutions for a problem guided by biological principles such as the survival of the fittest. This kind of techniques starts from a randomly generated population which evolves by means of crossover and mutation operations to provide the final solution.

Genetic Algorithm: A special type of evolutionary technique which represents the potential solutions of a problem within chromosomes (usually a collection of binary, natural or real values).

Multimodal Problems: A special kind of problems where a unique global solution does not exist. Several global optimums or one global optimum with several local optimums (or peaks) can be found around the search space.

Mutation: The other genetic operation included in evolutionary techniques to perform the reproduction stage. Mutation operator introduces new information in the system by random changes applied within the genetic individuals.

Search Space: Set of all possible situations of the problem that we want to solve could ever be in. Combination of all the possible values for all the variables related with the problem.

Species: Within the context of genetic algorithm, a subset of genetic individuals with similar genotype (genetic values) which explore the same, or a similar, area of the search space.

Full-Text Search Engines for Databases

László Kovács

University of Miskolc, Hungary

Domonkos Tikk

Budapest University of Technology and Economics, Hungary

INTRODUCTION

Current databases are able to store several Tbytes of free-text documents. The main purpose of a database from the user's viewpoint is the efficient information retrieval. In the case of textual data, information retrieval mostly concerns the selection and the ranking of documents. The selection criteria can contain elements that apply to the content or the grammar of the language. In the traditional database management systems (DBMS), text manipulation is restricted to the usual string manipulation facilities, i.e. the exact matching of substrings. Although the new SQL1999 standard enables the usage of more powerful regular expressions, this traditional approach has some major drawbacks. The traditional string-level operations are very costly for large documents as they work without task-oriented index structures.

The required full-text management operations belong to text mining, an interdisciplinary field of natural language processing and data mining. As the traditional DBMS engine is inefficient for these operations, database management systems are usually extended with a special full-text search (FTS) engine module. We present here the particular solution of Oracle; there for making the full-text querying more efficient, a special engine was developed that performs the preparation of full-text queries and provides a set of language and semantic specific query operators.

BACKGROUND

Traditional DBMS engines are not adequate to meet the users' requirements on the management of free-text data as they handle the whole text field as an atom (Codd, 1985). A special extension to the DBMS engine is needed for the efficient implementation of text manipulating operations. There is a significant demand

on the market on the usage of free text and text mining operations, since information is often stored as free text. Typical application areas are, e.g., text analysis in medical systems, analysis of customer feedbacks, and bibliographic databases. In these cases, a simple character-level string matching would retrieve only a fraction of related documents, thus an FTS engine is required that can identify the semantic similarities between terms.

There are several alternatives for implementing an FTS engine. In some DBMS products, such as Oracle, Microsoft SQLServer, Postgres, and MySQL, a built-in FTS engine module is implemented. Some other DBMS vendors extended the DBMS configuration with a DBMS-independent FTS engine. In this segment the main vendors are: SPSS LexiQuest (SPSS, 2007), SAS Text Miner (SAS, 2007), dtSearch (dtSearch, 2007), and Statistica Text Miner (Statsoft, 2007).

The market of FTS engines is very promising since the amount of textual information stored in databases rises steadily. According to the study of Meryll Lynch (Blumberg & Arte, 2003), 85% of business information are text documents – e-mails, business and research reports, memos, presentations, advertisements, news, etc. – and their proportion still increases. In 2006, there were more than 20 billion documents available on the Internet (Chang, 2006). The estimated size of the pool increases to 550 billion documents when the documents of the hidden (or deep) web – which are e.g. dynamically generated ones – are also considered.

TEXT MINING

The subfield of document management that aims at processing, searching, and analyzing text documents is *text mining*. The goal of text mining is to discover the non-trivial or hidden characteristics of individual documents or document collections. Text mining is an

Figure 1. The text mining module

application oriented interdisciplinary field of machine learning which exploits tools and resources from computational linguistics, natural language processing, information retrieval, and data mining.

The general application schema of text mining is depicted in Figure 1 (Fan, Wallace, Rich & Zhang, 2006). For giving a brief summary of text mining, four main areas are presented here: information extraction, text categorization/classification, document clustering, and summarization.

Information Extraction

The goal of information extraction (IE) is to collect the text fragments (facts, places, people, etc.) from documents relevant to the given application. The extracted information can be stored in structured databases. IE is typically applied in such processes where statistics, analyses, summaries, etc. should be retrieved from texts. IE includes the following subtasks:

- named entity recognition – recognition of specified types of entities in free text, see e.g. Borthwick, 1999; Sibanda & Uzuner, 2006,
- co-reference resolution – identification of text fragments referring to the same entity, see e.g. Ponzetto & Strube, 2006,
- identification of roles and their relations – determination of roles defined in event templates, see e.g. Ruppenhofer et al, 2006.

Text Categorization

Text categorization (TC) techniques aim at sorting documents into a given category system (see Sebastiani, 2002 for a good survey). In TC, usually, a classifier

model is built based on the content of a set of sample documents, which model is then used to classify unseen documents. Typical application examples of TC include among many others:

- document filtering – such as e.g. spam filtering, or newsfeed (Lewis, 1995);
- patent document routing – determination of experts in the given fields (Larkey, 1999);
- assisted categorization – helping domain experts in manual categorization with valuable suggestions (Tikk et al, 2007),
- automatic metadata generation (Liddy et al, 2002),

Document Clustering

Document clustering (DC) methods group elements of a document collection based on their similarity. Here again, documents are usually clustered based on their content. Depending on the nature of the results, one can have partitioning and hierarchical clustering methods. In the former case, there is no explicit relation among the clusters, while in the latter case a hierarchy of clusters is created. DC is applied for e.g.:

- clustering the results of (internet) search for helping users in locating information (Zamir et al, 1997),
- improving the speed of vector space based information retrieval (Manning et al, 2007),
- providing a navigation tool when browsing a document collection (Käki, 2005).

Summarization

Text summarization aims at the automatic generation of short and comprehensible summaries of documents. Text extraction algorithms create summary by extracting relevant descriptive phrases (typically sentences) from the original text, while summaries generated by abstraction methods may contain synthesized text as well. The typical application areas of summarization span from the internet search to arbitrary document management system (Ganapathiraju, 2002; Radev et al; 2001).

FULL-TEXT SEARCH (FTS) ENGINES

Full-Text Search

Based on the literature (Maier, 2001, Curtmola, 2005), an effective FTS engine should support several query functionalities. The simplest operation is the string-based query, which retrieves texts that exactly match the query string. In some cases, the position of the keywords within the document is also an important factor. The simplest form of similarity-based matching uses the edit-distance function. The next operation is the content-based query, where similarity is defined on the semantic level. An FTS engine should also support grammar (and therefore language) specific operators (e.g. stemming). The highest level of text search operates with semantic-based matching (thesaurus-based neighborhood, generalization of a word, specialization, synonyms). From the practical viewpoint, the efficient execution of queries is also very important. Due to the heterogeneity of the source pool, the support of different document formats is a key requirement. The minimal usage of other resources provides an independent, flexible solution. From the aspect of software development, the open, standardized interface is a good investment. To provide a manageable, easy to understand response, the efficient ranking of the result set is crucial (Chakrabarti, 2006). The products and test systems currently available only partially meet the above requirements.

Structure of a General FTS Engine

FTS engines are structurally similar to database systems: they store data and metadata; their purpose is to

provide an efficient information retrieval (Microsoft, 2007; Oracle Text, 2007). As the processing of a full-text query requires several distinct steps, the FTS engines typically have modular structure (see also Figure 2.).

The *loader* module loads the documents into a common staging area, into a common representation. In further steps, data items are transformed into a common format, too. The loaded documents are stored in the *datastore unit*. Document processing has several steps. The *sectioner unit* has to discover the larger internal logical structure of the documents. The *word-breaker* parses the text into smaller syntactical units like paragraphs, sentences and terms (words). For reducing the length and complexity of the text, several preprocessing steps are executed. First, a *filter module* is applied that discard irrelevant words (stop-words, noise words). Next, the *stemmer unit* generates the stem form for every word. In the background, the *language lexicon* supports the language-specific reduction steps. This lexicon contains the grammar of the supported languages and the list of stop-words. The thesaurus is a special lexicon, which stores the terms organized in a graph based on their semantic relationship. To provide an efficient term management, several kinds of indexes are created. The *indexer unit* manages the different document-term indices that enable the efficient access to term occurrences. On the front-end side, the *query preprocessor* transforms the user's query into an internal format. This format is processed by the *query matcher*, resulting in a set of matching documents. The search engine may be extended with a text mining module that performs data mining operations, like clustering or classification. In order to provide a more accurate response, the *query refinement engine* performs the processing of relevance feedback. The list of matching documents is pipelined to the *ranking module*. The *exporter module* generates the final format of the ranked document set.

As mentioned, database systems use indices for the fast access to data items. For full-text search, the inverted index is the most efficient index structure (Zobel, 2006). In the simple inverted index, the key of the index is the term. Each key is associated with a pair (*df*, *dl*). Here *df* is the number of documents containing the key, and *dl* is the list of documents that contain the key. Each entry in the list contains a document identifier and the frequency value in the document. The position-based inverted index differs from the simple version as that the list corresponding to a document also contains the positions of the given term in the text.

Figure 2. Modules of an FTS engine

FTS Engine Interface in Oracle Text

The FTS functionality in Oracle Text (Oracle, 2007) can be activated with some extensions to SQL and with procedural SQL packages. Oracle Text supports four index types:

- CONTEXT-type index: inverted index for long documents;
- CTXCAT-type index: to support content- and attribute-based indexing for shorter documents;
- CTXRULE-type index: rules for document clustering;
- CTXPATH-type index: indexing of XML documents.

The stemming module supports only two languages: English and French. In the queries, the CONTAINS operator supports the following matching modes:

- keyword: exact matching;
- AND, OR, NOT : Boolean operators;
- NEAR (keyword1, keyword2): the keywords should occur at near positions in the document;
- BT(keyword): generalization of the keyword;

- NT(keyword): specialization of the keyword;
- REL(keyword): words in the thesaurus in relation with the keyword;
- SYN(keyword): the synonyms of the keyword;
- \$keyword: words having the same stem;
- !keyword: words having the same pronunciation;
- ABOUT keywords: words belonging to the given topic;
- FUZZY(keyword): words that are close to the keyword in terms of the edit distance;
- WITHIN (section): the matching is restricted to a given section of the documents.

The example below retrieves the documents containing words that have similar meaning as “food”:

```
SELECT description FROM books WHERE CONTAINS (description, 'NT(food,1)') > 0;
```

Oracle Text supports three methods for document partition (categorization & clustering). The manual categorization allows the user to enter keyword-category pairs. The automatic categorization works if a training set of document-category pairs is given. The cluster-

ing method automatically determines the clusters in a set of documents based on their similarity. To provide semantic-based matching for any arbitrary domain, the users can create their own thesaurus.

FUTURE TRENDS

In our view, there are three main areas where the role of FTS engine should be improved in the future: web search engines, ontology-based information retrieval, and management of XML documents. The main standard for the query of XML documents is nowadays the XQuery language. This standard is very flexible for selecting structured data elements, but it has no special features for the unstructured part. In (Botev, 2004; Curtmola, 2005), an extension of XQuery with full-text functionality is proposed. The extended query language is called TeXQuery and GalaTex. The language contains a rich set of composite full-text primitives such as phrase matching, proximity distance, stemming and thesauri. The combination of structure- and content-based queries is investigated deeply from a theoretical viewpoint in (Amer, 2004).

The efficiency of information retrieval can be improved with the extension of additional semantic information. The ALVIS project (Luu, 2006) aims at building a distributed, peer-to-peer semantic search engine. The peer-to-peer network is a self-organizing system for decentralized data management in distributed environments. During a query operation, a peer broadcasts search requests in the network. A peer may be assigned to a subset of data items. The key element in the cost reduction is the application of a special index type at the nodes. The index contains in addition to the single keyword entries also entities for compound keys with high discriminative values.

A very important application area of full-text search is the Web. A special feature of Web search is that the users apply mostly simple queries. Only 10% of queries use some complex full-text primitives like Boolean operators, stemming or fuzzy matching. Eastman (2003) investigated the reasons of omitting the complex operators and concluded that the application of complex full-text operators does not significantly improve the search results. Efficiency is a key factor in web search engines (Silvestri, 2004). The goal of the research is to upgrade the indexing mechanism of web search engines to provide efficient full-text search

operators.

CONCLUSION

The information is stored on the web and in computers mostly in free-text format. The current databases are able to store and manage huge document collection. Free-text data sources require specific search operations. Database management systems usually contain a separate full-text search engine to perform full-text search primitives. In general, the current FTS engines support the following functionalities: exact matching, position-based matching, similarity-based matching (fuzzy matching), grammar-based matching (stemming) and semantic-based matching (synonym- and thesaurus-based matching). It has been shown that the average user requires additional help to exploit the benefits of these extra operators. Current research focuses on solving the problem of covering new document formats, adapting the query to the user's behavior, and providing an efficient FTS engine implementation.

KEY TERMS

Full-Text Search (FTS) Engine: A module within a database management system that supports efficient search in free texts. The main operations supported by the FTS engine are the exact matching, position-based matching, similarity-based matching, grammar-based matching and semantic-based matching.

Fuzzy Matching: A special type of matching where the similarity of two terms are calculated as the cost of the transformation from one into the other. The most widely used cost calculation method is the edit distance method.

Indexer: It builds one or more indices for the speed up information retrieval from free text. These indices usually contain the following information: terms (words), occurrence of the terms, format attributes.

Inverted Index: An index structure where every key value (term) is associated with a list of objects identifiers (representing documents). The list contains objects that include the given key value.

Query Refinement Engine: A component of the FTS engine that generates new refined queries to the initial query in order to improve the efficiency of the retrieval. The refined queries can be generated using the users' response or some typical patterns in the query history.

Ranking Engine: A module within the FTS engine that ranks the documents of the result set based on their relevance to the query.

Sectioner: A component of the FTS engine, which breaks the text into larger units called sections. The types of extracted sections are usually determined by the document type.

Stemmer: It is a language-dependent module that determines the stem form of a given word. The stem form is usually identical to the morphological root. It requires a language dictionary.

Thesaurus: A special repository of terms, which contains not only the words themselves but the similarity, the generalization and specialization relationships. It describes the context of a word but it does not give an explicit definition for the word.

Word-Braker: A component of the full-text engine whose function is to break the text into words and phrases.

Functional Dimension Reduction for Chemometrics

Tuomas Kärnä

Helsinki University of Technology, Finland

Amaury Lendasse

Helsinki University of Technology, Finland

INTRODUCTION

High dimensional data are becoming more and more common in data analysis. This is especially true in fields that are related to spectrometric data, such as chemometrics. Due to development of more accurate spectrometers one can obtain spectra of thousands of data points. Such a high dimensional data are problematic in machine learning due to increased computational time and the curse of dimensionality (Haykin, 1999; Verleysen & François, 2005; Bengio, Delalleau, & Le Roux, 2006).

It is therefore advisable to reduce the dimensionality of the data. In the case of chemometrics, the spectra are usually rather smooth and low on noise, so function fitting is a convenient tool for *dimensionality reduction*. The fitting is obtained by fixing a set of basis functions and computing the fitting weights according to the least squares error criterion.

This article describes a unsupervised method for finding a good function basis that is specifically built to suit the data set at hand. The basis consists of a set of Gaussian functions that are optimized for an accurate fitting. The obtained weights are further scaled using a Delta Test (DT) to improve the prediction performance. Least Squares Support Vector Machine (LS-SVM) model is used for estimation.

BACKGROUND

The approach where multivariate data are treated as functions instead of traditional discrete vectors is called Functional Data Analysis (FDA) (Ramsay & Silverman, 1997). A crucial part of FDA is the choice of basis functions which allows the functional representation. Commonly used bases are B-splines (Alsberg & Kvalheim, 1993), Fourier series or wavelets (Shao,

Leung, & Chau, 2003). However, it is appealing to build a problem-specific basis that employs the statistical properties of the data at hand.

In literature, there are examples of finding the optimal set of basis functions that minimize the fitting error, such as Functional Principal Component Analysis (Ramsay et al., 1997). The basis functions obtained by Functional PCA usually have global support (i.e. they are non-zero throughout the data interval). Thus these functions are not good for encoding spatial information of the data. The spatial information, however, may play a major role in many fields, such as spectroscopy. For example, often the measured spectra contain spikes at certain wavelengths that correspond to certain substances in the sample. Therefore these areas are bound to be relevant for estimating the quantity of these substances.

We propose that locally supported functions, such as Gaussian functions, can be used to encode this sort of spatial information. In addition, variable selection can be used to select the relevant functions from the irrelevant ones. Selecting important variables directly on the raw data is often difficult due to high dimensionality of data; computational cost of variable selection methods, such as Forward-Backward Selection (Benoudjit, Cools, Meurens, & Verleysen, 2004; Rossi, Lendasse, François, Wertz, & Verleysen, 2006), grows exponentially with the number of variables. Therefore, wisely placed Gaussian functions are proposed as a tool for encoding spatial information while reducing data dimensionality so that other more powerful information processing tools become feasible. Delta Test (DT) (Jones, 2004) based scaling of variables is suggested for improving the prediction performance.

A typical problem in chemometrics deals with predicting some chemical quantity directly from measured spectrum. Due to additivity of absorption spectra, the problem is assumed to be linear and therefore linear

models, such as Partial Least Squares (Härdle, Liang, & Gao, 2000) have been widely used for the prediction task. However, it has been shown that the additivity assumption is not always true and environmental conditions may further introduce more non-linearity to the data (Wülfert, Kok, & Smilde, 1998). We therefore propose that in order to address a general prediction problem, a non-linear method should be used. LS-SVM is a relatively fast and reliable non-linear model which has been applied to chemometrics as well (Chauchard, Cogdill, Roussel, Roger, & Bellon-Maurel, 2004).

USING GAUSSIAN BASIS WITH SPECTROMETRIC DATA

Consider a problem where the goal is to estimate a certain quantity $p \in \mathfrak{R}$ from a measured absorption spectrum X based on the set of N training examples $(X_j, p_j)_{j=1}^N$. In practice, the *spectrometric data* X_j is a set of discretized measurements $(x_i^j, y_i^j)_{i=1}^m$ where $x_i^j \in [a, b] \subset \mathfrak{R}$ stand for the observation wavelength and $y_i^j \in \mathfrak{R}$ is the response.

Adopting the FDA framework (Ramsay et al., 1997), our goal is to build a prediction model F so that $\hat{p} = F(X)$. Here, the argument X is a real-world spectrum, i.e. a continuous function that maps wavelengths to responses. Without much loss of generality it can be assumed that X belongs to $L_2([a, b])$, the space of square integrable functions on the interval $[a, b]$. However, since the spectrum X is unknown and infinite dimensional it is impossible to build the model $F(X)$ in practice. Therefore X must be approximated with a q dimensional representation $\omega = P(X)$, $P: L_2 \rightarrow \mathfrak{R}^q$, and our prediction model becomes $\hat{p} = F(\omega)$. Naturally, in order to obtain *dimensionality reduction*, we

require that q is smaller than the number of points in the spectra.

Figure 1 presents a graph of the overall prediction method. Gaussian fitting is used for the approximation of X . The obtained vectors ω are further scaled by a diagonal matrix A before the final LS-SVM modeling. The following sections explain these steps in greater detail.

Gaussian Fitting: Approximating Spectral Function X

Because the space $L_2([a, b])$ is infinite dimensional function space, it is necessary to consider some finite dimensional subspace $V \subset L_2([a, b])$ in order to obtain a feasible *function approximation*. We define V by a set of *Gaussian functions*

$$\phi_k(x) = e^{-\|x-t_k\|^2/\sigma_k^2}, k = 1, \dots, q, \quad (1)$$

where t_k is the center and σ_k is the width parameter. The set $\phi_k(x)$ spans a q dimensional normed vector space and we can write $V = \text{span}\{\phi_k(x)\}$. A natural choice for the norm is the L_2 norm:

$$\|\hat{f}\|_V = \left(\int_a^b \hat{f}(x)^2 dx \right)^{1/2}.$$

Now X can be approximated using the basis representation $\hat{X}(x) = \omega^T \phi(x)$, where

$$\phi(x) = [\phi_1(x), \phi_2(x), \dots, \phi_q(x)]^T.$$

The weights ω are chosen to minimize the square error:

Figure 1. Outline of the prediction method

$$\min_{\omega} \sum_{i=1}^m |y_i - \omega^T \phi(x_i)|^2 \quad (2)$$

In other words, we simply fit a function to the points $(x_i, y_i)_{i=1}^m$ using the **basis functions** $\phi_k(x)$. Now, any function $\hat{X} \in V$ is uniquely determined by the weight vector ω . This suggests that it is equivalent to analyze the discrete weight vectors ω instead of the continuous functions \hat{X} .

Orthonormalization

Radial symmetric models (such as the LS-SVM) depend only on the distance metric $d(\cdot, \cdot)$ in the input space. Thus, we require that the mapping from V to \mathfrak{R}^q is isometric, i.e. $d_V(\hat{f}, \hat{g}) = d_q(\alpha, \beta)$ for any functions $\hat{f}(x) = \alpha^T \phi(x)$ and $\hat{g}(x) = \beta^T \phi(x)$. The first distance is calculated in the function space and the latter one in \mathfrak{R}^q . In the space V , distances are defined by the norm $d(\hat{f}, \hat{g}) = \|\hat{f} - \hat{g}\|_V$. Now a simple calculation gives

$$\|\hat{f} - \hat{g}\|_V^2 = \int_a^b \left(\sum_{k=1}^q (\alpha - \beta) \phi_k(x) \right)^2 dx = (\alpha - \beta)^T \Phi (\alpha - \beta),$$

where

$$\Phi_{i,j} = \int_a^b \phi_i(x) \phi_j(x) dx.$$

This implies that if the **basis** is **orthonormal**, the matrix Φ becomes an identity matrix and the distances become equal, i.e.

$$\|\hat{f} - \hat{g}\|_V = \|\alpha - \beta\|_q = ((\alpha - \beta)^T (\alpha - \beta))^{1/2}.$$

Unfortunately this is not the case with Gaussian basis and a linear transformation $\tilde{\omega} = \mathbf{U}\omega$ need to be applied. Here the matrix \mathbf{U} is the Cholesky decomposition of $\Phi = \mathbf{U}^T \mathbf{U}$. In fact, the transformed weights ω are related to a set of new basis functions $\tilde{\phi} = \mathbf{U}^{-1} \phi$ that are both optimized to fit the data and orthonormal.

Finding an Optimal Gaussian Basis

When the **basis functions** are fixed, the weights ω are

obtained easily by solving the problem (2). The solution is the pseudoinverse $\omega = (\mathbf{G}^T \mathbf{G})^{-1} \mathbf{G}^T \mathbf{y}$ (Haykin, 1999), where $\mathbf{y} = [y_1, y_2, \dots, y_m]^T$ are the values to be fitted and $[\mathbf{G}]_{i,j} = \phi_j(x_i)$.

Since the **Gaussian functions** are differentiable, the locations and widths can be optimized for a better fit. The average fitting error of all functions is obtained by averaging Eq. (2) over all of the sample inputs $j = 1, \dots, N$. Using the matrix notation given above, it can be formulated as

$$E = \frac{1}{2N} \sum_{j=1}^N (\mathbf{G} \omega_j - \mathbf{y}_j)^T (\mathbf{G} \omega_j - \mathbf{y}_j),$$

which can be differentiated with respect to t_k and σ_k (Kärnä & Lendasse, 2007).

Knowing the partial derivatives, the locations and the widths can be optimized using unconstrained **non-linear optimization**. In this article, **Broyden-Fletcher-Goldfarb-Shanno (BFGS)** Quasi-Newton method with line search is suggested. The formulation of the BFGS algorithm can be found in Bazaraa, Sherali and Shetty (1993).

An example of spectral data and an optimized basis functions in presented in Figure 2. This application is

Figure 2. Above: NIR absorption spectra. Below: 13 optimized basis functions

related to prediction of fat content in meat samples using NIR absorption spectra (Kärnä et al., 2007; Rossi et al., 2006; Thodberg, 1996). It can be seen that the basis has adapted to the data: there are narrow functions in the center where there is more variance in the data.

Variable Scaling

Variable scaling can be seen as a generalization of variable selection; in variable selection variables are either included in the training set (corresponding to multiplication by 1) or excluded from it (corresponding to multiplication by 0), while in variable scaling the entire range $[0,1]$ of scalars is allowed. In this article, we present a method for choosing the scaling using Delta Test (DT) (Lendasse, Corona, Hao, Reyhani, & Verleysen, 2006).

The scalars are generated by iterative **Forward-Backward Selection** (FBS) (Benoudjit et al., 2004; Rossi et al., 2006). FBS is usually used for variable selection, but it can be extended to scaling as well; Instead of turning scalars from 0 to 1 or vice versa, increases by $1/h$ (in the case of forward selection) or decreases by $1/h$ (in the case of backward selection) are allowed. Integer h is a constant grid parameter. Starting from an initial scaling, the FBS algorithm changes the each of the scalars by $\pm 1/h$ and accepts the change that resulted in the best improvement. The process is repeated until no improvement is found. The process is initialized with several sets of random scalars.

DT is a method for estimating the variance of the noise within a data set. Having a set of general input-output pairs $(\mathbf{x}_i, y_i)_{i=1}^N \in \mathfrak{R}^m \times \mathfrak{R}$ and denoting the nearest neighbor of \mathbf{x}_i by $\mathbf{x}_{NN(i)}$ the DT variance estimate is

$$\delta = \frac{1}{2N} \sum_{i=1}^N |y_{NN(i)} - y_i|^2,$$

where $y_{NN(i)}$ is the output of $\mathbf{x}_{NN(i)}$. Thus, δ is equivalent to the residual (i.e. prediction error) of a first-nearest-neighbor model. DT is useful in evaluation of dependence of random variables and therefore it can be used for scaling: The set of scalars that give the smallest δ is selected.

LS-SVM

LS-SVM is a least square modification of the Support Vector Machine (SVM) (Suykens, Van Gestel, De

Brabanter, De Moor, & Vandewalle, 2002). The quadratic optimization problem of SVM is simplified so that it reduces into a linear set of equations. Moreover, regression SVM usually involves three unknown parameters while LS-SVM has only two; the regularization parameter γ and the width parameter θ .

Given a set of N training examples $(\mathbf{x}_i, y_i)_{i=1}^N \in \mathfrak{R}^m \times \mathfrak{R}$ the LS-SVM model is $\hat{y} = \mathbf{w}^T \psi(x) + b$, where $\psi: \mathfrak{R}^m \rightarrow \mathfrak{R}^n$ is a mapping from the input space onto a higher dimensional hidden space, $\mathbf{w} \in \mathfrak{R}^n$ is a weight vector and b is a bias term. The optimization problem is formulated as

$$\text{Min}_{\mathbf{w}, b} J(\mathbf{w}, b) = \frac{1}{2} \|\mathbf{w}\|^2 + \frac{1}{2} \gamma \sum_{i=1}^N e_i^2$$

so that $y_i = \mathbf{w}^T \psi(x_i) + b + e_i$,

where e_i is the prediction error and $\gamma \geq 0$ is a regularization parameter. The dual problem is derived using Lagrangian multipliers which lead into a linear KKT system that is easy to solve (Suykens et al., 2002). Using the dual solution, the original model can be reformatted as

$$\hat{y}(\mathbf{x}) = \sum_{i=1}^N \alpha_i K(\mathbf{x}, \mathbf{x}_i) + b,$$

where the kernel $K(\mathbf{x}, \mathbf{x}_i) = \psi(\mathbf{x})^T \psi(\mathbf{x}_i)$ is a continuous and symmetric mapping from $\mathfrak{R}^m \times \mathfrak{R}^m$ to \mathfrak{R} and α_i are the Lagrange multipliers. A widely-used choice for the K is the standard Gaussian kernel $K(\mathbf{x}_1, \mathbf{x}_2) = e^{-\|\mathbf{x}_1 - \mathbf{x}_2\|_2^2 / \theta^2}$.

The LS-SVM prediction is the final step in the proposed method where spectral data is compressed by the Gaussian fitting and the fitting weights are normalized and scaled before the prediction. More elaborate discussion and applications to real-world data are presented in Kärnä et al. (2007).

FUTURE TRENDS

The only unknown parameter in the proposed method is the number of basis functions which is selected by validation. In future other methods for determining good basis size should be developed in order to speed up the process. Moreover, the methodology should be tested with various data sets, including other than

spectral data. The LS-SVM predictor could be also replaced with another model.

Although the proposed Gaussian fitting combined with LS-SVM model seems to be fairly robust, the relation between the basis functions and the prediction performance should be studied in detail. It would be desirable to optimize the basis directly for best possible prediction performance (instead of good data fitting), although it seems difficult due to over-fitting and high computational costs.

CONCLUSION

This article deals with the problem of finding a good set of basis functions for dimension reduction of spectral data. We have proposed a method based on Gaussian basis functions where the locations and the widths of the functions are optimized to fit the data as accurately as possible. The basis indeed tends to follow the nature of the data and provides a good tool for dimension reduction. Other methods, such as the proposed DT scaling, will benefit from the smaller data dimension and help to achieve even better data compression. The LS-SVM model is a robust and fast method to be used in the final prediction.

KEY TERMS

Chemometrics: Application of mathematical or statistical methods to chemical data. Closely related to monitoring of chemical processes and instrument design.

Curse of Dimensionality: A theoretical result in machine learning that states that the lower bound of error that an adaptive machine can achieve increases with data dimension. Thus performance will degrade as data dimension grows.

Delta Test: A Non-parametric Noise Estimation method. Estimates the amount of noise within a data set, i.e. the amount of information that cannot be explained by any model. Therefore Delta Test can be used to obtain a lower bound of learning error which can be achieved without risk of over-fitting.

Functional Data Analysis: A statistical approach where multivariate data are treated as functions instead of discrete vectors.

Least Squares Support Vector Machine: A least squares modification of the Support Vector Machine which leads into solving a linear set of equations. Also bears close resemblance to Gaussian Processes.

Machine Learning: An area of Artificial Intelligence dealing with adaptive computational methods such as Artificial Neural Networks and Genetic Algorithms.

Over-Fitting: A common problem in Machine Learning where the training data can be explained well but the model is unable to generalize to new inputs. Over-fitting is related to the complexity of the model: any data set can be modelled perfectly with a model complex enough, but the risk of learning random features instead of meaningful causal features increases.

Support Vector Machine: A kernel based supervised learning method used for classification and regression. The data points are projected into a higher dimensional space where they are linearly separable. The projection is determined by the kernel function and a set of specifically selected support vectors. Training process involves solving a Quadratic Programming problem.

Variable Selection: Process where unrelated input variables are discarded from the data set. Variable selection is usually based on correlation or noise estimators of the input-output pairs and can lead into significant improvement in performance.

INTRODUCTION

Functional networks are a generalization of neural networks, which is achieved by using multiargument and learnable functions, i.e., in these networks the transfer functions associated with neurons are not fixed but learned from data. In addition, there is no need to include parameters to weigh links among neurons since their effect is subsumed by the neural functions. Another distinctive characteristic of these models is that the specification of the initial topology for a functional network could be based on the features of the problem we are facing. Therefore knowledge about the problem can guide the development of a network structure, although on the absence of this knowledge always a general model can be used.

In this article we present a review of the field of functional networks, which will be illustrated with practical examples.

BACKGROUND

Artificial Neural Networks (ANN) are a powerful tool to build systems able to learn and adapt to their environment, and they have been successfully applied in many fields. Their learning process consists of adjusting the values of their parameters, i.e., the weights connecting the network's neurons. This adaptation is carried out through a learning algorithm that tries to adjust some training data representing the problem to be learnt. This algorithm is guided by the minimization of some error function that measures how well the ANN is adjusting the training data (Bishop, 1995). This process is called parametric learning. One of the most popular neural

network models are Multilayer Perceptrons (MLP) for which many learning algorithms can be used: from the brilliant backpropagation (Rumelhart, Hinton & William, 1986) to the more complex and efficient Scale Conjugate Gradient (Möller, 1993) or Levenberg-Marquardt algorithms (Hagan & Menhaj, 1994).

In addition, also the topology of the network (number of layers, neurons, connections, activation functions, etc.) has to be determined. This is called *structural learning* and it is carried out mostly by trial and error.

As a result, there are two main drawbacks in dealing with neural networks:

1. The resulting function lacks of the possibility of a physical or engineering interpretation. In this sense, Neural Networks act as black boxes.
2. There is no guarantee that the weights provided by the learning algorithm correspond to a global optimum of the error function, it can be a local one.

Models like Generalized Linear Networks (GLN) present an unique global optimum that can be obtained by solving a set of linear equations. However, its mapping function is limited as this model consists of a single layer of adaptive weights (w_j) to produce a linear combination of non linear functions (ϕ_j):

$$y(\mathbf{x}) = \sum_{j=0}^M w_j \phi_j(\mathbf{x}).$$

Some other popular models are Radial Basis Function Networks (RBF) whose hidden units use distances to a prototype vector (μ_j) followed by a transformation with a localized function like the Gaussian:

$$y(\mathbf{x}) = \sum_{j=0}^M w_j \phi_j(\mathbf{x}) = \sum_{j=0}^M w_j \exp\left(-\frac{\|\mathbf{x} - \mathbf{x}_j\|^2}{2\sigma_j^2}\right)$$

The resulting architecture is more simple than the one of the MLP, therefore reducing the complexity of structural learning and propitiating the possibility of physical interpretation. However, they present some other limitations like their inability to distinguish non significant input variables (Bishop, 1995), to learn some logic transformations (Moody & Darken, 1989) or the need of a large number of nodes even for a linear map if precision requirement is high (Youssef, 1993).

Due to these limitations, there have been appearing some models that extend the original ANN, such as, fuzzy neural networks (Gupta & Rao, 1994), growing neural networks, or probabilistic neural networks (Specht, 1990). Nowadays, the majority of these models still act as black boxes. Functional networks (Castillo, 1998, Castillo, Cobo, Gutiérrez, & Pruneda, 1998), a relatively new extension of neural networks, take into account the functional structure and properties of the process being modeled, that naturally determine the initial network's structure. Moreover, the estimation of the network's weights it is often based on an error function that can be minimized by solving a system of linear equations, therefore conducting faster to an unique and global solution.

NETWORKS

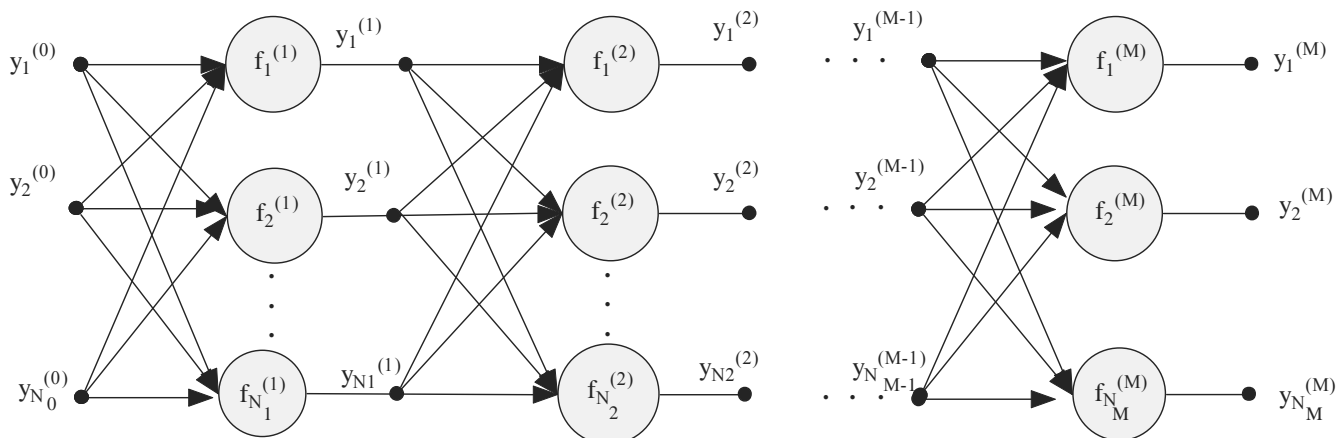

Functional networks (FN) are a generalization of neural networks, which is achieved by using multiargument and learnable functions (Castillo, 1998, Castillo, Cobo, Gutiérrez, & Pruneda, 1998), i.e., the shape of the functions associated with neurons are not fixed but learned from data. In this case, it is not necessary to include weights to ponder links among neurons since their effect is subsumed by the neural functions. Figure 1 shows an example of a general FN for $I=N_0$ explanatory variables.

Functional networks consist of the following elements:

- Several layers of storing units (represented in Figure 1 by small filled circles). These units are used for the storage of both the input and the output of the network, or to storage intermediate information (see units $y_i^{(k)}$ in Figure 1).
- One or more layers of functional units or neurons (represented by open circles with the name of each of the functional units inside). These neurons include a function that can be multivariate and that can have as many arguments as inputs. These arguments, and therefore the form of the neural functions, are learnt during training. By applying their functions, neurons evaluate a set of input

DESCRIPTION OF FUNCTIONAL

Figure 1. Generalized model for functional networks

values in order to return a set of output values to the next layer of storing units. In this general model each neural function $f_i^{(m)}$ is defined as the following composition:

$$f_i^{(m)}(y_1^{(m-1)}, \dots, y_{N_{m-1}}^{(m-1)}) = g_i^{(m)}(h_{i1}^{(m-1)}(y_1^{(m-1)}), \dots, h_{iN_{m-1}}^{(m-1)}(y_{N_{m-1}}^{(m-1)}))$$

where the superscript (m) is the number of layer. The functions $g_i^{(m)}$ are known and fixed before training, for example to be the sum or product. In contrast, functions $h_{ij}^{(m)}$ are lineal combinations of other known functions ϕ_{ij} (for example, polynomials, cosines, etc.), i.e. $h_{ij}^{(m)}(y_j^{(m-1)}) = \sum_{z=1}^{n_{ij}^{(m)}} a_{ijz}^{(m)} \phi_{ijz}(y_j^{(m-1)})$ where the coefficients $a_{ijz}^{(m)}$ implied in this linear combination are the model parameters to be learned. As can be observed, MLPs, GLNs and RBFs are particular cases of this generalized model.

- c. A set of directed links that connect the functional units and the storing units. These connections indicate the direction of the flow of information. The general FN in Figure 1 does not have arrows that converge in the same storing unit, but if it did, this would indicate that the neurons from which they emanate must produce identical outputs. This is an important feature of FNs that is not available for neural networks. These converging arrows represent constraints which can arise from physical and/or theoretical characteristics of the problem under consideration.

Learning in Functional Networks

Functional networks combine knowledge about the problem to determine the network, and training data to estimate the unknown neural functions. Therefore, in contradistinction to neural networks, FNs include two types of learning:

1. *Structural learning*. The specification of the initial topology for a FN can be based on the features of the problem we are facing (Castillo, Cobo, Gutiérrez, & Pruneda, 1998). Usually knowledge about the problem can be used in order to develop a network structure. An important feature of FN is that they allow managing functional restric-

tions determined by some known properties of the model to be estimated. These restrictions can be representing by forcing the outputs of some neurons to coincide in a unique storage unit. Later on, the network can be translated into a system of functional equations that usually can be simplified in order to obtain a more simple but equivalent architecture. Finally, on the absence of knowledge about the problem always the general model, shown in Figure 1, can be used.

2. *Parametric learning*. This second stage refers to the estimation of the neuron's functions. Often these neural functions are considered to be lineal combinations of functional families, and therefore the parametric learning consists of estimating both the arguments of the neural functions and the parameters of the lineal combination using the available training data. It is important to remark that this type of learning generalizes the idea of estimating the weights of a neural network.

An Example Of A Functional Network

In this section the use of FNs is illustrated by means of an artificial simple example. Let's suppose a problem of engine diagnosis for which three continuous variables (x = 'vibrations', y = 'oil density', z = 'temperature') are being monitored. The problem is to estimate the probability P of a given diagnosis based on these variables, i.e., $P(x, y, z)$. Moreover, we know that the information provided by the monitored variables is accumulative. Therefore, it is possible, for example, to calculate first the probability $P_1(x, y)$ of a diagnosis based on only variables x and y , and later on when variable z is available combine the value provided by P_1 with the new information z to obtain $P(x, y, z)$. That is, there exist some functions such as:

$$P(x, y, z) = F[P_1(x, y), z] = K[P_2(y, z), x] = L[P_3(x, z), y] \quad (1)$$

This situation suggests the structure of the FN shown in Figure 2a, where I is the identity function. The coincident connections in the store output unit, or equivalently eq. 1, establish strong restrictions about the functions P_1, P_2, P_3, F, K, L . The use of methods for functional equations allows to deal with eq. 1 in order to obtain the corresponding functional conditions from which it is possible to derive a new equation for

Figure 2. Functional network for the diagnosis example

function P :

$$P(x, y, z) = k[p(x) + q(y) + g(z)].$$

This leads to the new more simple FN represented in Figure 2b which is equivalent to that of Figure 2a.

A Comparison Between Functional and Neural Networks

Although FNs are extensions of neural networks, there are some main features that distinguish both models:

1. Neural networks are derived only from data about the problem. However, FNs can also use knowledge about the problem to derive its topology, incorporating properties about the function to be modeled.
2. During learning in neural networks the shape of neural functions is fixed usually to be a sigmoid type function, and only the weights can be adapted. In FNs, neural functions are also learnt.
3. Neural functions that can be employed in neural networks are limited and belong to some known

family. Also, for each layer the same function is used for every neuron. In FNs any arbitrary function can be used for each neuron.

4. These functions can be multiargument and multivariate. In neural networks activation functions have only one argument (combination of several input data).
5. In FNs it is possible to force the output of some neurons to coincide by connecting them to the same storing unit. These connections are restrictions to the model that sometimes can be used to derive a more simple model.

Some Functional Network Models

In this section some typical FN models are presented, that let solving several real problems.

The Uniqueness Model

This is a simple but very powerful model for which the output z of the corresponding FN architecture can be written as a function of the inputs x and y ,

$$z = F(x, y) = f_3^{-1}(f_1(x) + f_2(y)) \quad (2)$$

Uniqueness of Representation. For this model to have uniqueness of solution it is only required to fix the functions f_1, f_2, f_3 at a point (see explanation in Castillo, Cobo, Gutiérrez, & Pruneda, 1998).

Learning the model. Learning the function $F(x, y)$ in eq.2 is equivalent to learning the functions from a data set, $\{(x_j, y_j, z_j): j = 1, \dots, n\}$ where z is the desired output for the given inputs. To estimate f_1, f_2, f_3 we can employ the non-linear and linear methods:

1. **The Non-Linear Method.** We approximate each of the functions $f_1, f_2, f_3^{-1} z = F(x, y) = f_3^{-1}(f_1(x) + f_2(y))$ by considering them to be a linear combination of known functions from a given family (e. g., polynomial). Finally, the following sum of squared errors is minimized,

$$Q = \sum_{j=1}^n e_j^2 =$$

$$\sum_{j=1}^n \left(z_j - \sum_{k=1}^{m_3} a_{3k} \phi_{3k} \left(\sum_{i=1}^{m_1} a_{1i} \phi_{1i}(x_j) + \sum_{i=1}^{m_2} a_{2i} \phi_{2i}(y_j) \right) \right)^2$$

2. **Linear Method.** A simplification of the non-linear method can be done by considering the following equivalence:

$$z_j = f_3^{-1}(f_1(x_j) + f_2(y_j)) \Leftrightarrow$$

$$f_3(z_j) = f_1(x_j) + f_2(y_j); j = 1, \dots, n$$

Again the functions f_s can be approximated as a linear combination of known functions from a given family. Finally, the following sum of square errors,

$$Q = \sum_{j=1}^n e_j^2 =$$

$$\sum_{j=1}^n \left(\sum_{i=1}^{m_1} a_{1i} \phi_{1i}(x_j) + \sum_{i=1}^{m_2} a_{2i} \phi_{2i}(y_j) - \sum_{i=1}^{m_3} a_{3i} \phi_{3i}(z_j) \right)^2$$

can be minimized by solving a system of linear equations, where the unknowns are the coefficients a_{si} as it is demonstrated in (Castillo, Cobo, Gutiérrez, & Pruneda, 1998).

The Generalized Associativity Model

Figure 3a shows a generalized associativity FN of three inputs, where the nodes I represent the identity function. This model is based on the generalized associative property, that is, the output of this network can be obtained as a function of $G(x, y)$ and the input z , or

Figure 3. The generalized associativity functional network

as a function of the input x and $N(y, z)$. This property is represented with the links convergent to the output node u , which leads to the functional equation

$$F[G(x, y), z] = K[x, N(y, z)] \quad (3)$$

Simplification of the model. It can be shown that the general solution of eq. 3 is:

$$\begin{aligned} F(x, y) &= k[f(x) + r(y)] \\ G(x, y) &= f^{-1}[p(x) + q(y)] \\ K(x, y) &= k[p(x) + n(y)] \\ N(x, y) &= n^{-1}[q(x) + r(y)] \end{aligned} \quad (4)$$

where f, r, k, n, p, q are arbitrary continuous and strictly monotonic functions. Substituting eq. 4 in eq. 3, the following result is obtained

$$F[G(x, y), z] = K[x, N(y, z)] = u = k[p(x) + q(y) + r(z)] \quad (5)$$

Thus, the FN in Figure 3b is equivalent to the FN in Figure 3a.

Uniqueness of Representation. By employing functional equations for the generalized associativity model it can be demonstrated that uniqueness of solution requires fixing the functions k, p, q, r at a point (see Castillo, Cobo, Gutiérrez, & Pruneda, 1998).

Learning the model. The problem of learning the FN in Figure 3b involves estimating the functions k, p, q, r in eq. 5, that can be rewritten as:

$$k^{-1}(u) = p(x) + q(y) + r(z)$$

Being $\{(x_{1i}, x_{2i}, x_{3i}, x_{4i}) | i = 1, \dots, n\}$ with $(x_1, x_2, x_3, x_4 \equiv x, y, z, u)$ the observed training sample of size n we can define the error

$$e_i = \hat{p}(x_{1i}) + \hat{q}(x_{2i}) + \hat{r}(x_{3i}) - \hat{k}^{-1}(x_{4i}); i = 1, \dots, n$$

Figure 4. Separable functional network architecture

Suppose that each of the functions is a linear combination of known functions from given families (e.g. polynomial). Then, the sum of squared errors is defined as

$$Q = \sum_{i=1}^n e_i^2 = \sum_{i=1}^n \left(\sum_{k=1}^4 \sum_{j=1}^{m_k} a_{kj} \phi_{kj}(x_{ki}) \right)^2$$

Employing the Lagrange multipliers technique, the minimum is obtained by solving the following system of linear equations:

$$\begin{aligned} \frac{\partial Q}{\partial a_{kr}} &= 2 \sum_{i=1}^n e_i \phi_{kr}(x_{ki}) + \lambda_k \phi_{kr}(\alpha_k) = 0; \forall k, r \\ \frac{\partial Q}{\partial \lambda_k} &= \sum_{j=1}^{m_k} a_{kj} \phi_{kj}(\alpha_k) - \beta_k = 0; \forall k, \end{aligned}$$

where the unknowns are the multipliers $\lambda_1, \dots, \lambda_4$ the coefficients in the set $\{a_{kj} \mid j=1, \dots, m_k; k=1, 2, 3, 4\}$ which are the parameters of the FN.

The Separable Model

Consider the equation

$$z = F(x, y) = \sum_{i=1}^n f_i(x) r_i(y) = \sum_{j=1}^m h_j(x) k_j(y),$$

which can be written as

$$\sum_{i=1}^k f_i(x) g_i(y) = 0 \quad (6)$$

where

$$\begin{aligned} f_i(x) &= h_{i-n}(x) \\ g_i(y) &= -k_{i-n}(y); i = n+1, \dots, n+m \end{aligned}$$

This suggests the FN in Figure 4a.

Simplification of the model. Assuming that $\{f_1(x), \dots, f_r(x)\}, \{g_{r+1}(x), \dots, g_k(x)\}$ are two sets of linearly independent functions, the general solution of eq. 6

$$\sum_{i=1}^k f_i(x) g_i(y) = 0$$

is

$$\begin{aligned} f_j(x) &= \sum_{j=1}^r a_{jk} f_k(x); j = r+1, \dots, k, \\ g_s(y) &= -\sum_{j=1}^{k-r} a_{js} g_{r+j}(y); s = 1, \dots, r \end{aligned}$$

By replacing these terms in equation eq. 6 we obtain

$$z = F(x, y) = \sum_{i=1}^r \sum_{j=1}^{k-r} c_{ij} f_i(x) g_j(y) \quad (7)$$

where c_{ij} are the parameters of the model, and which leads to the simplified FN in Figure 4b.

Uniqueness of Representation. In this case the uniqueness of representation is given without the need of fixing the implied functions at any point.

Learning the model. In this case a simple least squares method allows obtaining the optimal coefficients c_{ij} using the available data $\{(x_{0i}, x_{1i}, x_{2i}) \mid i = 1, \dots, n\}$ with $(x_0, x_1, x_2) \equiv (z, x, y)$. In this way, the error can be obtained as,

$$e_i = x_{0i} - \sum_{j=1}^r \sum_{j=1}^{s-r} c_{ij} f_j(x_{1i}) g_j(x_{2i}); i = 1, \dots, n$$

Thus, to find the optimum coefficients we minimize the sum of squared errors

$$Q = \sum_{k=1}^n e_k^2$$

In this case, the parameters are not constrained by extra conditions, so the minimum can be obtained by solving the following system of linear equations, where the unknowns are the coefficients c_{ij} :

$$\begin{aligned} \frac{\partial Q}{\partial c_{pq}} &= 2 \sum_{k=1}^n e_k f_p(x_{1k}) g_q(x_{2k}) = 0; \\ p &= 1, \dots, r; q = 1, \dots, r-s \end{aligned}$$

Examples of Applications

In this section, illustrative examples for two different models of FN are presented. These models were ap-

plied to a regression and a classification problem. In all cases, the functions of each layer were approximated by considering a linear combination of known functions from a polynomial family.

Classification Problem

The first example shows the performance of a FN solving a classification problem: the Wine data set. This database can be obtained from the UCI Machine Learning Repository¹. The aim of this problem is to determine the origin of wines using a chemical analysis of 13

continuous attributes. The set contains 178 instances that must be classified in three different classes.

For this case, the Separable Model (Figure 4) with three output units was employed. Moreover, its performance is compared to other standard methods: a Multilayer Perceptron (MLP), a Radial Basis Function Network (RBF) and Support Vector Machines (SVM).

Figure 5 shows the comparative results. The first subfigure contains the mean accuracy obtained using a leaving-one-out cross-validation method. As can be observed, the FN obtains a very good performance for

Figure 5. Accuracy and training time obtained by different models for the wine data set

the test set. Regarding the time required for the learning process, the second subfigure shows that the FNs are comparable with the other methods.

Regression Problem

In this case the aim of the network is to predict the failure shear effort in concrete beams based on several geometrical, longitudinal and transversal parameters of the beam (Alonso-Betanzos, Castillo, Fontenla-Romero, & Sánchez-Maróño, 2004).

A FN, corresponding to the Associative Model (Figure 3), and also a MLP were trained employing a ten-fold cross-validation, running 30 simulations using different initial parameter values. A set with 12 samples was kept for further validation of the trained systems. The mean normalized Mean Squared Errors over 30 simulations obtained by the FN was 0.1789 and 0.8460 for test and validation, respectively, while the MLP obtained 0.1361 and 2.9265.

FUTURE TRENDS

Functional networks are being successfully employed in many different real applications. In engineering problems they have been applied, for instance, for surface reconstruction (Iglesias, Gálvez, & Echevarría, 2006). Other works have used these networks for recovering missing data (Castillo, Sánchez-Maróño, Alonso-Betanzos, & Castillo, 2003) and for general regression and classification problems (Lacruz, Pérez-Palomares & Pruneda, 2006).

Another recent research line is related to the investigation of measures of fault tolerance (Fontenla-Romero, Castillo, Alonso-Betanzos, & Guijarro-Berdiñas, 2004), in order to develop new learning methods.

CONCLUSION

This article presents a review of functional networks. Functional networks are inspired by neural networks and functional equations. This model offers all the advantages of ANNs, such as noise tolerance and generalisation capacity, adding new advantages. One of them is the possibility to use knowledge about the problem to be modeled to derive the initial network topology, thus resulting on a model that can be physical

or engineering interpreted. Another main advantage is that the initially proposed model can be simplified, using functional equations, and learnt by solving a system of linear equations, which speeds the learning process and avoid it to be stuck in a local minimum. Finally, the shape of neural function does not have to be fixed, but they can be fitted from data during training, therefore widening the modeling ability of the network.

KEY TERMS

Error Function: When talking about learning, this is a function that quantifies how much a system has learnt. One of the most popular error functions is the mean squared error that measures the differences between the answers provided by a system and the correct answer.

Functional Equation: An equation for which its unknowns are expressed in terms of both independent variables and functions.

Functional Network: A structure consisting of processing units and storing units. These units are organized in layers and linked by connections. Each processing unit contains a multivariate and multiargument function to be learnt during a training process.

Lagrange Multiplier: Given the function $f(x_1, x_2, \dots, x_n)$, the Lagrange multiplier λ is used to find the extremum of f subject to a constraint $g(x_1, x_2, \dots, x_n)$ by solving

$$\frac{\partial f}{\partial x_k} + \lambda \frac{\partial g}{\partial x_k} = 0, \forall k = 1, \dots, n$$

Learning Algorithm: A process that, based on some training data representing the problem to be learnt, adapts the free parameters of a given model, such as a neural network, in order to obtain a desired functionality.

Linear Equation: An algebraic equation involving only a constant and first-order (linear) terms.

Uniqueness: Property of being the only possible solution.

Fuzzy Approximation of DES State

Juan Carlos González-Castolo

CINVESTAV Unidad Guadalajara, Mexico

Ernesto López-Mellado

CINVESTAV Unidad Guadalajara, Mexico

INTRODUCTION

State estimation of dynamic systems is a resort often used when only a subset of the state variables can be directly measured; observers are the entities computing the system state from the knowledge of its internal structure and its (partially) measured behaviour. The problem of discrete event systems (DES) estimation has been addressed in (Ramirez, 2003) and (Giua 2003); in these works the marking of a Petri net (PN) model of a partially observed event driven system is computed from the evolution of its inputs and outputs.

The state of a system can be also inferred using the knowledge on the duration of activities. However this task becomes complex when, besides the absence of sensors, the durations of the operations are uncertain; in this situation the observer obtains and revise a belief that approximates the current system state. Consequently this approach is useful for non critical applications of state monitoring and feedback in which an approximate computation is allowed.

The uncertainty of activities duration in DES can be handled using fuzzy PN (FPN) (Murata, 1996), (Cardoso, 1999), (Hennequin, 2001), (Pedrycz, 2003), (Ding, 2005); this PN extension has been applied to knowledge modelling (Chen, 1990), (Koriam, 2000), (Shen, 2003), planning (Cao, 1996), reasoning (Gao, 2003) and controller design (Andreu, 1997), (Leslaw, 2004).

In these works the proposed techniques include the computation of imprecise markings; however the class of models dealt does not include strongly connected PN for the modelling of cyclic behaviour. In this article we address the problem of state estimation of DES for calculating the fuzzy marking of a Fuzzy Timed Petri Net (FTPN); for this purpose a set of matrix expressions for the recursive computing the current fuzzy marking is developed. The article focuses on FTPN whose structure is a Marked Graph (called Fuzzy Timed Marked

Graph -FTMG) because it allows showing intuitively the problems of the marking estimation in exhibiting cyclic behaviour.

BACKGROUND

Possibility Theory

In theory of possibility, a fuzzy set \tilde{a} is used for delimiting ill-known values or for representing values characterized by symbolic expressions. The set is defined as $\tilde{a} = (a_1, a_2, a_3, a_4)$ such that $a_1, a_2, a_3, a_4 \in \mathbb{R}$, $a_1 \leq a_2$ and $a_3 \leq a_4$. The fuzzy set \tilde{a} delimits the run time as follows:

- The values $\tilde{\tau}_b, \tilde{\tau}_a$ in the ranges $(a_1, a_2), (a_3, a_4)$, respectively, indicate that the activity is possibly executed with $\alpha(\tau) \in (0, 1)$. When $\tau \in \tilde{\tau}_b$ the function $\alpha(\tau)$ grows towards 1, which means that the possibility of stopping increases. When $\tau \in \tilde{\tau}_a$, the membership function $\alpha(\tau)$ decreases towards 0, representing that there is a reduction of the possibility of stopping.
- The values $(0, a_1]$ mean that the activity is running.
- The values $[a_4, +\infty)$ mean that the activity is stopped.
- The values $\tilde{\tau}_a \in [a_2, a_3]$ $| a_2 \leq a_3$ represent full possibility that is $\alpha(\tau) = 1$, this represents that it is certain that the activity is stopped.
- The support of \tilde{a} is the range $\tau \in [a_1, a_4]$ where $\alpha_{\tilde{a}}(\tau) > 0$.

A fuzzy set \tilde{a} is referred indistinctly by the function $\alpha(\tau)$ or the characterization (a_1, a_2, a_3, a_4) . For simplicity, in this work the fuzzy possibility distribution of the time is described with trapezoidal or triangular forms. For example, Fig.1 shows the fuzzy set that

Figure 1. Fuzzy set

it is represents in natural language: “the activity will stop about 2.5”.

Fuzzy extension principle. The fuzzy extension principle plays a fundamental role because we can extend functions defined on crisp sets to functions on fuzzy sets. An important application of this principle is a mechanism to operate arithmetically with fuzzy numbers.

Definition. Let X_1, \dots, X_n be crisp sets and let f a function such $f: X_1 \times \dots \times X_n \rightarrow Y$. If $\tilde{a}_1, \dots, \tilde{a}_n$ are fuzzy sets on X_1, \dots, X_n , respectively, then $f(\tilde{a}_1, \dots, \tilde{a}_n)$ is the fuzzy set on Y such that:

$$f(\tilde{a}_1, \dots, \tilde{a}_n) = \cup_{(x_1, \dots, x_n) \in (X_1 \times \dots \times X_n)} \{ \alpha_{\tilde{a}_1}(x_1) \wedge \dots \wedge \alpha_{\tilde{a}_n}(x_n) / f(x_1, \dots, x_n) \}$$

If $\tilde{b} = f(\tilde{a}_1, \dots, \tilde{a}_n)$ then \tilde{b} is the fuzzy set on Y such that:

$$\tilde{b}(y) = \vee_{(x_1, \dots, x_n) \in (X_1 \times \dots \times X_n) : f(x_1, \dots, x_n) = y} [\alpha_{\tilde{a}_1}(x_1) \wedge \dots \wedge \alpha_{\tilde{a}_n}(x_n)]$$

The fuzzy set was characterized as:

$$\tilde{a} = \{ \alpha_{\tilde{a}}(x_1) / x_1, \dots, \alpha_{\tilde{a}}(x_n) / x_n \}$$

With the extension principle we can define a simplified fuzzy sets addition operation.

Definition. Let $\tilde{a} = (a_1, a_2, a_3, a_4)$ and $\tilde{b} = (b_1, b_2, b_3, b_4)$ be two trapezoidal fuzzy sets. The fuzzy sets addition operation is: $\tilde{a} \oplus \tilde{b} = (a_1 + b_1, a_2 + b_2, a_3 + b_3, a_4 + b_4)$ (Klir, 1995).

Definition The intersection and union of fuzzy sets are defined in terms of min and max operators.

$$(\tilde{a} \cap \tilde{b}) = \min(\tilde{a}, \tilde{b}) = \min(\alpha_{\tilde{a}}(\tau), \alpha_{\tilde{b}}(\tau)) \mid \tau \in \text{support_of_} \tilde{a} \wedge \tilde{b}$$

and

$$(\tilde{a} \cup \tilde{b}) = \max(\tilde{a}, \tilde{b}) = \max(\alpha_{\tilde{a}}(\tau), \alpha_{\tilde{b}}(\tau)) \mid \tau \in \text{support_of_} \tilde{a} \vee \tilde{b}$$

We used these operators, intersection and union, as a t-norm and a s-norm, respectively.

Definition The distribution of possibility before and after \tilde{a} are the fuzzy sets $\tilde{a}^b = (-\infty, a_2, a_3, a_4)$ and $\tilde{a}^a = (a_1, a_2, a_3, +\infty)$ respectively; they are defined in (Andreu, 1997) as a function $\alpha_{(-\infty, \tilde{a}]}(\tau) = \sup_{\tau' \geq \tau} \alpha(\tau')$ and $\alpha_{[\tilde{a}, +\infty]}(\tau) = \sup_{\tau' \leq \tau} \alpha(\tau')$, respectively.

Petri Nets Theory

Definition. An ordinary PN structure G is a bipartite digraph represented by the 4-tuple $G = (P, T, I, O)$ where $P = \{p_1, p_2, \dots, p_n\}$ and $T = \{t_1, t_2, \dots, t_m\}$ are finite sets of vertices called respectively places and transitions, $I(O): P \times T \rightarrow \{0, 1\}$ is a function representing the arcs going from places to transitions (transitions to places).

Pictorially, places are represented by circles, transitions are represented by rectangles, and arcs are depicted as arrows. The symbol $\bullet_j(t_j \bullet)$ denotes the set

of all places p_i such that $I(p_i, t_j) \neq 0$ ($O(p_i, t_j) \neq 0$). Analogously, $\bullet p_i$ ($p_i \bullet$) denotes the set of all transitions t_j such that $O(p_i, t_j) \neq 0$ ($I(p_i, t_j) \neq 0$).

The pre-incidence matrix of G is $C^- = [c_{ij}^-]$ where $c_{ij}^- = I(p_i, t_j)$; the post-incidence matrix of G is $C^+ = [c_{ij}^+]$ where $c_{ij}^+ = O(p_i, t_j)$; the incidence matrix of G is $C = C^+ - C^-$.

A marking function $M: P \rightarrow \mathbb{Z}^+$ represents the number of tokens or marks (depicted as dots) residing inside each place. The marking of a PN is usually expressed as an n-entry vector.

Definition. A Petri Net system or Petri Net (PN) is the pair $N = (G, M_0)$, where G is a PN structure and M_0 is an initial token distribution.

In a PN system, a transition t_j is enabled at the marking M_k if $\forall p_i \in P, M_k(p_i) \geq I(p_i, t_j)$; an enabled transition t_j can be fired reaching a new marking M_{k+1} which can be computed using the PN state equation:

$$M_{k+1} = M_k + C^+ v_k - C^- v_k \quad (1)$$

where $v_k(i) = 0, i \neq j, v_k(j) = 1$.

The reachability set of a PN is the set of all possible reachable marking from M_0 firing only enabled transitions; this set is denoted by $R(G, M_0)$.

A structural conflict is a PN sub-structure in which two or more transitions share one or more input places; such transitions are simultaneously enabled and the firing of one of them may disable the others, Fig.3(b).

Definition. A transition $t_k \in T$ is live, for a marking M_0 , if $\forall M_k \in R(G, M_0), \exists M_n \in R(G, M_0)$ such that t_k is enabled

$$\left(M_n \xrightarrow{t_k} \right).$$

A PN is live if all its transitions are live.

Definition. A PN is said 1-bounded, or safe, for a marking M_0 , if $\forall p_i \in P$ and $\forall M_j \in R(G, M_0)$, it holds that $M_j(p_i) \leq 1$.

In this work we deal with live and safe PN.

Definition. A p -invariant Y_i (t -invariant X_i) of a PN is a positive integer solution of the equation $Y_i^T C = 0$ ($C X_i = 0$). The support of the p -invariant Y_i (t -invariant X_i) is the set $\|Y_i\| = \{p_j \mid Y_i(p_j) \neq 0\}$ ($\|X_i\| = \{t_j \mid X_i(t_j) \neq 0\}$)

Definition. Let Y_i a p -invariant of a Petri net (G, M_0) , $\|Y_i\|$ the support of Y_i , then the induced subnet by Y_i is

$$PC_i = (P_i = \|Y_i\|, T_i = \cup t_k \in \bullet p_j, t_l \in p_j \bullet \mid p_j \in \|Y_i\|, I_i, O_i)$$

named p -component, where

$$I_i = P_i \times T_i \cap I, \quad O_i = P_i \times T_i \cap O.$$

Definition. Let X_i be a t -invariant of a PN, and $\|X_i\|$ be the support of X_i , then the induced subnet by X_i is

$$TC_i = (P_i = \{ \cup p_k \in \bullet t_j, p_l \in t_j \bullet \mid t_j \in \|X_i\| \}, T_i = \|X_i\|, I_i, O_i)$$

named t -component.

$$I_i = P_i \times T_i \cap I \quad \text{and} \quad O_i = P_i \times T_i \cap O.$$

Definition. A invariant Z_i is minimal if no invariant Z_j satisfies $\|Z_j\| \subset \|Z_i\|$, where Z_i, Z_j are p -invariants or t -invariants and $\forall z \in Z_i: z \geq 0$.

Definition. Let $Z = \{Z_1, \dots, Z_q\}$ be the set of minimal invariants (Silva, 1982) of a PN, then Z is called the invariants base. The cardinality of Z is represented as $|Z|$.

FUZZY TIMED PETRI NETS

Basic Operators

We introduce first some useful operators.

Definition. In order to get the fuzzy set between \tilde{f} and \tilde{g} , the lmax function is defined as:

$$lmax(\tilde{f}, \tilde{g}) = \min(\tilde{f}^a, \tilde{g}^b) \quad (2)$$

Definition. The latest (earliest) operation selects the latest (earliest) fuzzy set among n fuzzy sets; they are calculated as follows:

$$\begin{aligned} latest(\tilde{f}_1, \dots, \tilde{f}_n) = \\ \min(\max(\tilde{f}_1^b, \dots, \tilde{f}_n^b), \min(\tilde{f}_1^a, \dots, \tilde{f}_n^a)) \end{aligned} \quad (3)$$

$$\begin{aligned} earliest(\tilde{f}_1, \dots, \tilde{f}_n) = \\ \min(\min(\tilde{f}_1^b, \dots, \tilde{f}_n^b), \max(\tilde{f}_1^a, \dots, \tilde{f}_n^a)) \end{aligned} \quad (4)$$

Definition. The fuzzy_conjugation-operator is defined as $\arg 1 \bullet_{oper} \arg 2$, where $\arg 1, \arg 2$ are arguments that can be matrices of fuzzy sets; \bullet is the fuzzy and operation and $oper$ is any operation referred as, $+$, $-$, latest, min, etc. For some row $i = 1, \dots, m$ and some column $j = 1, \dots, n$ the products and $(\tilde{f}_{ik}, \tilde{g}_{kj}) | k = 1, \dots, r$ are computed as $oper(\text{and}(\tilde{f}_{ik}, \tilde{g}_{kj}))$. For example:

$$\begin{bmatrix} \tilde{f}_{11} & \dots & \tilde{f}_{1r} \\ \vdots & \ddots & \vdots \\ \tilde{f}_{m1} & \dots & \tilde{f}_{mr} \end{bmatrix} + \begin{bmatrix} \tilde{g}_{11} & \dots & \tilde{g}_{1n} \\ \vdots & \ddots & \vdots \\ \tilde{g}_{r1} & \dots & \tilde{g}_{rn} \end{bmatrix} =$$

$$\begin{bmatrix} \sum_{k=1}^r \tilde{f}_{1k} \tilde{g}_{k1} & \dots & \sum_{k=1}^r \tilde{f}_{1k} \tilde{g}_{kn} \\ \vdots & \ddots & \vdots \\ \sum_{k=1}^r \tilde{f}_{mk} \tilde{g}_{k1} & \dots & \sum_{k=1}^r \tilde{f}_{mk} \tilde{g}_{kn} \end{bmatrix}$$

Formalism Description of the FTPN

Definition. A fuzzy timed Petri net structure is a 3-tuple $FTPN = (N, \Gamma, \xi)$; where $N = (G, M_0)$ is a PN, $\Gamma = \{\tilde{a}_1, \tilde{a}_2, \dots, \tilde{a}_n\}$ is a collection of fuzzy sets, $\xi : P \rightarrow \Gamma$ is a function that associates a fuzzy set $\tilde{a}_i \in \Gamma$ to each place $p_i \in P$.

- Fuzzy timing of places

The fuzzy set $\tilde{a} = (a_1, a_2, a_3, a_4)$ Fig.2(b) represents the static possibility distribution $\alpha(\tau_a) \in [0, 1]$ of the instant at which a token leaves a place $p \in P$, starting from the instant when p is marked. This set does not change during the FTPN execution.

- Fuzzy timing of tokens

The fuzzy set $\tilde{b} = (b_1, b_2, b_3, b_4)$ Fig.2(c) represents the dynamic possibility distribution $\beta(\tau_b) \in [0, 1]$ associated to a token residing within a $p \in P$; it also represents the instant τ_b at which such a token leaves the place, starting from the instant when p is marked. \tilde{b} is computed from \tilde{a} every time the place is marked

Figure 2. (a) Fuzzy timed Petri net. (b) The fuzzy set associated to places. (c) Fuzzy set to place or mark associated. (d) Fuzzy timestamp

during the marking evolution of the FTPN. A token begins to be available for enabling output transitions at $\beta(b_1)$. Thus $\tilde{b}^a = (b_1, b_2, b_3, +\infty)$ represents the possibility distribution of available tokens. The fuzzy set $\tilde{c} = (c_1, c_2, c_3, c_4)$, known as *fuzzy timestamp*, Fig.2(d) is a dynamic possibility distribution $\varsigma(\tau_c) \in [0,1]$ that represents the duration of a token within a place $p \in P$.

Enabling and Firing of Transitions

- Fuzzy enabling date

The fuzzy enabling date $e_{t_k}(\tau)$ of the transition t_k at the instant τ is a possibility distribution of the latest leaving instant among the leaving instants \tilde{b}_{p_i} of all tokens within the $p_i \in \bullet t_k$, Fig.3(a).

$$e_{t_k}(\tau) = \text{latest}(\tilde{b}_{p_i}) \forall p_i \in \bullet t_k \quad (5)$$

The *latest* operation obtains the latest date in which the input places p_i to t_k have a token.

- Fuzzy firing date

The firing transition date $o_{t_k}(\tau)$ of a transition t_k is determined with respect to the set of transitions $\{t_j\}$ simultaneously enabled, Fig.3(b). This date, expressed as a possibility distribution, is computed as follows:

$$o_{t_k}(\tau) = \min(e_{t_k}(\tau), \text{earliest}(e_{t_j}(\tau)) \forall t_k \in p_n \bullet; p_n \in \bullet t_j) \quad (6)$$

The *earliest* operation obtains the earliest date in which the transitions in a structural conflict are enabled.

- Fuzzy timestamp

For a given place p_s , the possibility distribution \tilde{b}_{p_s} may be computed from a_{p_s} and the firing dates $o_{t_j}(\tau)$ of a $t_j \in \bullet p_s$ using the following expression:

$$\tilde{b}_{p_s} = \text{lmax}(o_{t_j}(\tau)) \oplus \tilde{a}_{p_s} \forall t_j \in \bullet p_s \quad (7)$$

The token do not disappear of $\bullet t$ and appear in $t \bullet$ instantaneously. The fuzzy timestamp \tilde{c}_{p_s} is the time elapse possibility that a token is in a place $p_s \in P$. The possibility distribution \tilde{c}_{p_s} is computed from the occurrence dates of both $\bullet p_s$ and $p_s \bullet$, see Fig.3(c).

$$c_{p_s} = \text{lmax}(\text{earliest}(o_{t_i}(\tau)), \text{latest}(o_{t_j}(\tau))) \forall t_i \in \bullet p_s, t_j \in p_s \bullet \quad (8)$$

Actually, \tilde{c}_{p_s} represent the fuzzy marking at the instant τ .

Matrix Formulation

Now, we reformulate the expressions (5), (6), (7) and (8) allowing a more general an compact representation.

$$\tilde{B} = \left(C^+ \bullet \tilde{O} \right) \oplus \tilde{A} \quad (9)$$

$$\tilde{E} = \left[C^- \right]^T \bullet \tilde{B} \quad (10)$$

$$\tilde{O} = \left[C^- \right]^T \bullet \left(C^- \bullet \tilde{E} \right) \quad (11)$$

Figure 3. (a) Conjunction transition. (b) Structural conflict. (c) Attribution and selection place

$$\tilde{C} = lmax \left(C^+ \bullet^{earliest} \tilde{O}, C^- \bullet^{latest} \tilde{O} \right) \quad (12)$$

where $\tilde{B}, \tilde{E}, \tilde{O}$ and \tilde{C} denote vectors composed by $\tilde{b}_{p_s}, \tilde{e}_{t_k}, \tilde{o}_{t_k}, \tilde{c}_{p_s}$, respectively.

Modeling Example

Now we will illustrate the previous matrix formulation though a simple example.

Example

Consider the system shown in Fig.4(a); it consist of two cars, car1 and car2, which move along independent and dependent ways executing the set of activities $Op = \{\text{Right_car1}, \text{Right_car2}, \text{Charge_car1}, \text{Charge_car2}, \text{Left_car1,2}, \text{Discharge_car1,2}\}$. The operation of the system is automated following the sequence described in the FTPN of Fig.4(b) in which the activities are associated to places. The ending time possibility \tilde{a}_{p_i} for every activity is given in the model. We are considering that there are not sensors detecting the tokens in the system, thus the behavior is then analyzed through the estimated state.

- Initial conditions: Initially, $M_0 = \{p_1\}$, therefore, the enabling date $e_{t_1}(\tau)$ of transitions t_1 is immediate, i.e., $(0,0,0,0)$. Since $|\bullet t_1| = 1$, then $o_{t_1}(\tau) = e_{t_1}(\tau)$.
- Matrix equations: For the obtained the fuzzy sets we solve (9)-(12) as follows:

$$\tilde{B} = \begin{bmatrix} \tilde{b}_{p_1} \\ \tilde{b}_{p_2} \\ \tilde{b}_{p_3} \\ \tilde{b}_{p_4} \\ \tilde{b}_{p_5} \\ \tilde{b}_{p_6} \end{bmatrix} = \begin{bmatrix} o_{t_5} \oplus \tilde{a}_{p_1} \\ o_{t_1} \oplus \tilde{a}_{p_2} \\ o_{t_1} \oplus \tilde{a}_{p_3} \\ o_{t_2} \oplus \tilde{a}_{p_4} \\ o_{t_3} \oplus \tilde{a}_{p_5} \\ o_{t_4} \oplus \tilde{a}_{p_6} \end{bmatrix} \quad (13)$$

$$\tilde{E} = \begin{bmatrix} e_{t_1} \\ e_{t_2} \\ e_{t_3} \\ e_{t_4} \\ e_{t_5} \end{bmatrix} = \begin{bmatrix} \tilde{b}_{p_1} \\ \tilde{b}_{p_2} \\ \tilde{b}_{p_3} \\ latest(\tilde{b}_{p_4}, \tilde{b}_{p_5}) \\ \tilde{b}_{p_6} \end{bmatrix} \quad (14)$$

$$\tilde{O} = \begin{bmatrix} o_{t_1} \\ o_{t_2} \\ o_{t_3} \\ o_{t_4} \\ o_{t_5} \end{bmatrix} = \begin{bmatrix} e_{t_1} \\ e_{t_2} \\ e_{t_3} \\ e_{t_4} \\ e_{t_5} \end{bmatrix} \quad (15)$$

Figure 4. (a) Two cars system. (b) Fuzzy timed Petri net model

$$\tilde{C} = \begin{bmatrix} \tilde{c}_{p_1} \\ \tilde{c}_{p_2} \\ \tilde{c}_{p_3} \\ \tilde{c}_{p_4} \\ \tilde{c}_{p_5} \\ \tilde{c}_{p_6} \end{bmatrix} = \begin{bmatrix} lmax(o_{t_5}, o_{t_1}) \\ lmax(o_{t_1}, o_{t_2}) \\ lmax(o_{t_1}, o_{t_3}) \\ lmax(o_{t_2}, o_{t_4}) \\ lmax(o_{t_3}, o_{t_4}) \\ lmax(o_{t_4}, o_{t_5}) \end{bmatrix} \quad (16)$$

- c. Firing t_1 : When t_1 is fired, the token is removed from p_1 ; p_2 and p_3 get one token each one.

$$\tilde{B} = [0 \quad (0.9, 1, 1, 1.1) \quad (0.8, 1, 1, 1.2) \quad 0 \quad 0 \quad 0]^T$$

The possibility sets \tilde{b}_{p_2} , \tilde{b}_{p_3} coincide with \tilde{a}_{p_2} and \tilde{a}_{p_3} , respectively.

- d. Firing t_2 : The fuzzy enabling time and the fuzzy occurrence time are computed by (14) and (15), respectively.

$$\tilde{O}, \tilde{E} = [0 \quad (0.9, 1, 1, 1.1) \quad 0 \quad 0 \quad 0]^T$$

The set \tilde{c}_{p_2} is the possibility distribution of the time at which p_2 is marked. So, we computed (16).

$$\tilde{C} = [0 \quad (0, 0, 1, 1, 1) \quad 0 \quad 0 \quad 0]^T$$

The set \tilde{b}_{p_4} is the possibility distribution of the instant at which place p_4 losses the token and it can be calculated by (13).

$$\tilde{B} = [0 \quad 0 \quad 0 \quad (2.6, 3, 3, 3.4) \quad 0 \quad 0]^T$$

- e. Firing t_3 : Again, using (14), (15) and (16) we obtain:

$$\tilde{O}, \tilde{E} = [0 \quad 0 \quad (0.8, 1, 1, 1.2) \quad 0 \quad 0]^T$$

$$\tilde{C} = [0 \quad 0 \quad (0, 0, 1, 1, 2) \quad 0 \quad 0 \quad 0]^T$$

$$\tilde{B} = [0 \quad 0 \quad 0 \quad 0 \quad (2.6, 3, 3, 3.4) \quad 0]^T$$

Figure 5(a) present the marking evolution of one cycle and some more steps. \tilde{C} is represented by the dashed line and \tilde{B} is represented by the shadowed area. Notice that \tilde{O} coincide sometimes with \tilde{B} .

FUZZY STATE EQUATION

We analyzed equation (1) in order to obtain the fuzzy marking equation. $C^+ v_k$ provides information about the places that get tokens. Also, we must consider that in FTPN the transition firing possibility evolves continuously. The variation of $O(\tilde{\tau}_b)$ during $\tau \in \tilde{\tau}_b$ modifies the possibility of tokens residing in the output places of the firing transitions; thus the corresponding term to v_k in FTPN is rather a variation denoted by $\Delta_{\tilde{O}(\tilde{\tau}_b)}$; thus the marking variation is $C^+ \Delta_{\tilde{O}(\tilde{\tau}_b)}$. By a similar reasoning on the term $C^- v_k$ corresponds to $C^- \Delta_{\tilde{O}(\tilde{\tau}_a)}$ in FTPN. The operation $C^+ \Delta_{\tilde{O}(\tilde{\tau}_b)} - C^- \Delta_{\tilde{O}(\tilde{\tau}_a)}$ represents the possible marking change. Considering the marking after a time elapse $\Delta\tau$ we obtain:

$$M(\tau) = M(\tau - \Delta\tau) + C^+ \Delta_{\tilde{O}(\tilde{\tau}_b)} - C^- \Delta_{\tilde{O}(\tilde{\tau}_a)} \quad (17)$$

Here

$$\Delta_{\tilde{O}(\tilde{\tau}_b)} = \tilde{O}(\tau) - \tilde{O}(\tau - \Delta\tau) \mid (\tau - \Delta\tau, \tau) \in \tilde{\tau}_b$$

and

$$\Delta_{\tilde{O}(\tilde{\tau}_a)} = \tilde{O}(\tau - \Delta\tau) - \tilde{O}(\tau) \mid (\tau - \Delta\tau, \tau) \in \tilde{\tau}_a.$$

The marking possibility obtained in (17) can be greater than 1; then since FTPN are safe, we use the min function to obtain $M(\tau) \leq 1$.

The new marking is denoted by $\hat{M}(\tau)$, i.e.,

$$\hat{M}(\tau) = \min(M(\tau - \Delta\tau) + C^+ \Delta_{\tilde{O}(\tilde{\tau}_b)} - C^- \Delta_{\tilde{O}(\tilde{\tau}_a)}, \bar{1}) \quad (18)$$

where $\bar{1}$ is a n-entry vector containing 1 in each entry.

Initially $M(0) = M_0$. If $\tau \neq 0$ then (18) is solved in three steps:

- $\tilde{M}(\tau) = C^+ \Delta_{\tilde{O}(\tilde{\tau}_b)} - C^- \Delta_{\tilde{O}(\tilde{\tau}_a)}$
- $M(\tau) = M(\tau - \Delta\tau) + \tilde{M}(\tau)$

$$\hat{M}(\tau) = \min(M(\tau), \bar{1})$$

Remark.

If $\Delta_{\tilde{\sigma}(\tau_b)}, \Delta_{\tilde{\sigma}(\tau_a)} \in \{0,1\}$ the behaviour is that of an ordinary timed Petri net.

Example.

For the system shown in Fig.4, we obtained the marking in some instants. The initial marking is $M(0) = [1 \ 0 \ 0 \ 0 \ 0 \ 0]$. The transition t_1 is firing at $\tau = 0^+$, therefore $M(0^+) = [0 \ 1 \ 1 \ 0 \ 0 \ 0]$. For $\tau \in (0^+, 0.8)$ the marking does not change. For $\tau = 1$ we obtain:

$$\tilde{M}(1) = \begin{bmatrix} 0 & 0 & 0 & 0 & 1 \\ 1 & 0 & 0 & 0 & 0 \\ 1 & 0 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 1 & 0 \end{bmatrix} \begin{bmatrix} 0 \\ 1 \\ 0 \\ 0 \\ 0 \\ 0 \end{bmatrix} - \begin{bmatrix} 1 & 0 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 0 & 1 \end{bmatrix} \begin{bmatrix} 0 \\ 0 \\ 0 \\ 0 \\ 0 \\ 0 \end{bmatrix}$$

$$M(1) = M(0.8) + \tilde{M}(1) = [0 \ 1 \ 1 \ 1 \ 0 \ 0]^T$$

$$\hat{M}(1) = \min(M(1), \bar{1}) = [0 \ 1 \ 1 \ 1 \ 0 \ 0]^T$$

The marking evolution at some relevant instants is shown below:

| t | 0 | 0.8 | 1 | 2 | 2.8 | 3 | 3.2 | 4 | 5 |
|-----------------------|---|-----|---|---|-----|------|-----|---|---|
| $\hat{M}_{p_1}(\tau)$ | 1 | 0 | 0 | 0 | 0 | 0 | 0 | 0 | 1 |
| $\hat{M}_{p_2}(\tau)$ | 0 | 1 | 1 | 0 | 0 | 0 | 0 | 0 | 0 |
| $\hat{M}_{p_3}(\tau)$ | 0 | 1 | 1 | 0 | 0 | 0 | 0 | 0 | 0 |
| $\hat{M}_{p_4}(\tau)$ | 0 | 0 | 1 | 1 | 1 | 1 | 0.5 | 0 | 0 |
| $\hat{M}_{p_5}(\tau)$ | 0 | 0 | 1 | 1 | 1 | 1 | 0.5 | 0 | 0 |
| $\hat{M}_{p_6}(\tau)$ | 0 | 0 | 0 | 0 | 0 | 0.66 | 1 | 1 | 1 |

Notice that during $\tau \in (0, 5)$, $\hat{M}(\tau)$ coincides with the fuzzy timestamp; it is shown in Fig.5(a).

STATE APPROXIMATION OF THE FTPN

Marking Estimation

Definition. The marking estimation Ξ in the instant τ is described by the function $\psi_{Y_i}(\tau) \in [0,1]$ which recognize the possible marked place $p_u \in \|Y_i\| \mid i \in \{1, \dots, |Y|\}$, among other possible places $p_v \in \|Y_i\| \mid v \neq u$. The function $\psi_{Y_i}(\tau)$ evaluates the minimal difference that exist

among the bigger possibility $\hat{M}_u(\tau)$ that the token is in a place u and the possibility $\hat{M}_v(\tau)$ that the token is in any other place. The function $\psi_{Y_i}(\tau)$ is then calculated.

$$\psi_{Y_i}(\tau) = \min(\|\hat{M}_{p_u}(\tau) - \hat{M}_{p_v}(\tau)\|) \quad (19)$$

such that $\forall \{p_u, p_v\} \in \|Y_i\|; v \neq u; Y_i \in Y$

Example.

The FTPN in Fig.4 has two p-invariants with supports $Y_1 = \|p_1, p_2, p_4, p_5\|$ and $Y_2 = \|p_1, p_3, p_5\|$. Figure 6 shows the fuzzy sets \tilde{C} obtained from evolution of the marking in the p-component induced by Y_i , Fig.5(b).

Definition. The state estimation S , at the instant τ is described by the function $s(\tau) \in [0,1]$, which determines the possible state of the system among other possible states; it is calculated by:

$$s(\tau) = \min(\psi_{Y_i}(\tau)) \mid i = 1, \dots, |Y|; Y_i \in Y \quad (20)$$

Discrete State From the FTPN

In order to obtain a possible discrete marking $\bar{M}(\tau)$ of the FTPN it is necessary to perform a “defuzzification” of $M(\tau)$. This can be accomplished taking into account the possible discrete marking $\bar{M}_i(\tau)$ of every p-component induced by Y_i . Before describing the procedure to obtain $\bar{M}(\tau)$, we define $M(\tau)$ as:

$$M(\tau) = [m_{p_1}(\tau) \dots m_{p_n}(\tau)]^T \mid n = |P| \quad (21)$$

where $m_{p_k}(\tau) \mid k = 1, \dots, n$ is the estimated marking of the place $p_k \in P$. Now, the discrete marking can be obtained with the following procedure.

Algorithm: Defuzzification

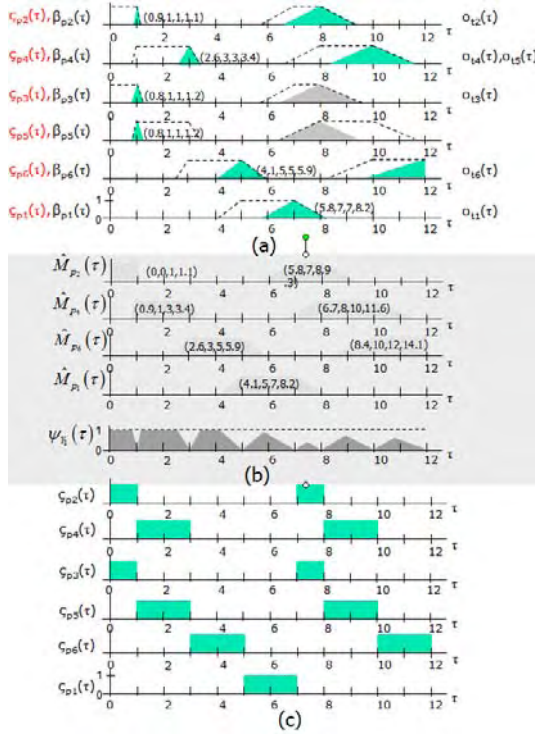

See Algorithm A.

Example.

Following the previous example, the marking $M(\tau)$ during $\tau \in (0, 0.8]$ does not change, that is

$$\bar{M}(\tau) = M_{0^+} = [0 \ 1 \ 1 \ 0 \ 0 \ 0]$$

Figure 5. (a) Fuzzy marking evolution. (b) Marking estimation. (c) Discrete state

For $\tau = 0.95$ the new fuzzy marking is

$$M(0.95) = [0 \quad 1 \quad 1 \quad 0.5 \quad 0.25 \quad 0]^T,$$

therefore

$$\begin{aligned} \bar{M}_1(0.95) &= [0 \quad 1 \quad 0 \quad 0 \quad 0 \quad 0]^T & \bar{M}_2(0.95) &= [0 \quad 0 \quad 1 \quad 0 \quad 0 \quad 0]^T \\ \hat{M}(0.95) &= [0 \quad 1 \quad 0 \quad 0 \quad 0 \quad 0]^T + [0 \quad 0 \quad 1 \quad 0 \quad 0 \quad 0]^T = [0 \quad 1 \quad 1 \quad 0 \quad 0 \quad 0]^T \\ \bar{M}(0.95) &= [0 \quad 1 \quad 1 \quad 0 \quad 0 \quad 0]^T \end{aligned}$$

Figure 5(c) shows the marking obtained at different instants.

FUTURE TRENDS

Previous results on estimation of Fuzzy Timed State Machines and that included in this article are going to be integrated for addressing a larger class of PN.

Another issue currently addressed is the study of FTPN including measurable places for dealing with sensors or detectable activities within the system; this will allow establishing a bound on the uncertainty of the estimated state. The optimal placement of sensors is an interesting matter of research.

Algorithm A.

Input: $M(\tau), Y$

Output: $\bar{M}(\tau)$

Step 1 $\bar{M}(\tau) \leftarrow \vec{0}$

Step 2 $\forall Y_i \mid i = 1, \dots, |Y|$

Step 2.1 $\forall p_k \in Y_i : \hat{m}_q = \max(\bar{M}(p_k))$

Step 2.2 $\bar{M}(p_q) = 1$

The aim of this research has been the use of the methodology for estimating the DES state of a discrete event system for monitoring its behavior and diagnosing faults. A FTPN is going to be used as a reference model and their outputs (measurable marking) have to be compared with the outputs of the monitored system; the analysis of residuals should provide an early detection of system malfunctioning and a plausible location of the faulty behavior.

CONCLUSION

This article addressed the state estimation problem of DES whose the duration of activities is ill known; fuzzy sets represent the uncertainty of the ending of activities. Several novel notions have been introduced in the FTPN definition, and a new matrix formulation for computing the fuzzy marking of Marked Graphs has been proposed. The extreme situation in which any activity of a system cannot be detected by sensors has been dealt for illustrating the degradation of the marking estimation when a cyclic execution is performed. Current research addresses the topics mentioned in the above section.

KEY TERMS

Discrete Events Systems: It is the class of systems whose behavior is characterized by successions of states delimited by asynchronous events. Most of these systems have been man made.

Fuzzy Logic: It is a Knowledge representation technique and computing framework whose approach is based on degrees of truth rather than the usual “true” or “false” of classical logic.

Fuzzy Petri Nets: It is a family of formalisms extending Petri nets by the inclusion of fuzzy sets representing usually uncertainty of time elapses.

Imprecise Marking: The imprecise localization of tokens within places of a FTPN; it is computed as a possibility distribution.

Petri Nets: It is a family of formalisms for modeling and analysis of concurrent DES allowing intuitive graphical descriptions and providing a simple but sound mathematical support. A timed Petri net includes information about the duration of the modeled activities.

Marked Graph: It is a Petri Net subclass in which every place has only one input transition and one output transition.

State Estimation: It is the inference process that determines the current state of a system from the knowledge of sequences of inputs and outputs.

State Machine: It is a Petri Net subclass in which every transition has only one input place and one output place.

System Monitoring: It is a surveillance process on measurable events and/or outputs of a system; it is often used a reference model that specifies a reasonable good behavior. Deviations from the reference are analyzed and determined if there exist a fault. This process is included as a part of a fault diagnosis process.

Fuzzy Control Systems: An Introduction

Guanrong Chen

City University of Hong Kong, China

Young Hoon Joo

Kunsan National University, Korea

INTRODUCTION

Fuzzy control systems are developed based on fuzzy set theory, attributed to Lotfi A. Zadeh (Zadeh, 1965, 1973), which extends the classical set theory with memberships of its elements described by the classical characteristic function (either “is” or “is not” a member of the set), to allow for partial membership described by a membership function (both “is” and “is not” a member of the set at the same time, with a certain degree of belonging to the set). Thus, fuzzy set theory has great capabilities and flexibilities in solving many real-world problems which classical set theory does not intend or fails to handle.

Fuzzy set theory was applied to control systems theory and engineering almost immediately after its birth. Advances in modern computer technology continuously backs up the fuzzy framework for coping with engineering systems of a broad spectrum, including many control systems that are too complex or too imprecise to tackle by conventional control theories and techniques.

BACKGROUND: FUZZY CONTROL SYSTEMS

The main signature of fuzzy logic technology is its ability of suggesting an approximate solution to an imprecisely formulated problem. From this point of view, fuzzy logic is closer to human reasoning than the classical logic, where the latter attempts to precisely formulate and exactly solve a mathematical or technical problem if ever possible.

Motivations for Fuzzy Control Systems Theory

Conventional control systems theory, developed based on classical mathematics and the two-valued logic, is relatively mature and complete. This theory has its solid foundation built on classical mathematics, electrical engineering, and computer technology. It can provide rigorous analysis and often perfect solutions when a system is precisely defined mathematically. Within this framework, some relatively advanced control techniques such as adaptive, robust and nonlinear control theories have gained rapid development in the last three decades.

However, conventional control theory is quite limited in modeling and controlling complex dynamical systems, particularly ill-formulated and partially-described physical systems. Fuzzy logic control theory, on the contrary, has shown potential in these kinds of non-traditional applications. Fuzzy logic technology allows the designers to build controllers even when their understanding of the system is still in a vague, incomplete, and developing phase, and such situations are quite common in industrial control practice.

General Structure of Fuzzy Control Systems

Just like other mathematical tools, fuzzy logic, fuzzy set theory, fuzzy modeling, fuzzy control methods, etc., have been developed for solving practical problems. In control systems theory, if the fuzzy interpretation of a real-world problem is correct and if fuzzy theory is developed appropriately, then fuzzy controllers can be suitably designed and they work quite well to their advantages. The entire process is then returned to the

original real-world setting, to accomplish the desired system automation. This is the so-called “fuzzification—fuzzy operation—defuzzification” routine in fuzzy control design. The key step—fuzzy operation—is executed by a logical rule base consisting of some IF-THEN rules established by using fuzzy logic and human knowledge (Chen & Pham, 1999, 2006; Drianker, Hellendoorn & Reinfrank, 1993; Passino & Yurkovich, 1998; Tanaka, 1996; Tanaka & wang, 1999; Wang, 1994; Ying, 2000).

Fuzzification

Fuzzy set theory allows partial membership of an element with respect to a set: an element can partially belong to a set and meanwhile partially not belong to the same set. For example, an element, x , belonging to the set, X , IS specified by a (normalized) membership function, $\mu_x : X \rightarrow [0,1]$. There are two extreme cases: $\mu_x(x) = 0$ means $x \notin X$ and $\mu_x(x) = 1$ means $x \in X$ in the classical sense. But $\mu_x(x) = 0.2$ means x belongs to X only with grade 0.2, or equivalently, x does not belong to X with grade 0.8. Moreover, an element can have more than one membership value at the same time, such as $\mu_x(x) = 0.2$ and $\mu_x(x) = 0.6$, and they need not be summed up to one. The entire setting depends on how large the set X is (or the sets X and Y are) for the associate members, and what kind of shape a membership function should have in order to make sense of the real problem at hand. A set, X , along with a membership function defined on it, $\mu_x(\cdot)$, is called a *fuzzy set* and is denoted (X, μ_x) . More examples of fuzzy sets can be seen below, as the discussion continues. This process of transforming a crisp value of an element (say $x = 0.3$) to a fuzzy set (say $x = 0.3 \in X = [0,1]$ with $\mu_x(x) = 0.2$) is called *fuzzification*.

Given a set of real numbers, $X = [-1,1]$, a point $x \in X$ assumes a real value, say $x = 0.3$. This is a crisp number without fuzziness. However, if a membership function $\mu_x(\cdot)$ is introduced to associate with the set X , then (X, μ_x) becomes a fuzzy set, and the (same) point $x = 0.3$ has a membership grade quantified by $\mu_x(\cdot)$ (for instance, $\mu_x(x) = 0.9$). As a result, x has not one but two values associated with the point: $x = 0.3$ and $\mu_x(x) = 0.9$. In this sense, x is said to have been *fuzzified*. For convenience, instead of saying that “ x is in the set X with a membership value $\mu_x(x)$,” in common practice it is usually said “ x is,” while one should keep in mind that there is always a well-defined membership function

associated with the set X . If a member, x , belongs to two fuzzy sets, one says “ x is X_1 AND x is X_2 ,” and so on. Here, the relation AND needs a logical operation to perform. As a result, this statement eventually yields only one membership value for the element x , denoted by $\mu_{x_1 \times x_2}(x)$. There are several logical operations to implement the logical AND; they are quite different but all valid within their individual logical system. A commonly used one is $\mu_{x_1 \times x_2}(x) = \min \{ \mu_{x_1}(x), \mu_{x_2}(x) \}$.

Fuzzy Logic Rule Base

The majority of fuzzy logic control systems are knowledge-based systems. This means that either their fuzzy models or their fuzzy logic controllers are described by fuzzy logic IF-THEN rules. These rules have to be established based on human expert’s knowledge about the system, the controller, and the performance specifications, etc., and they must be implemented by performing rigorous logical operations.

For example, a car driver knows that if the car moves straight ahead then he does not need to do anything; if the car turns to the right then he needs to steer the car to the left; if the car turns to the right by too much then he needs to take a stronger action to steer the car to the left much more, and so on. Here, “much” and “more” etc. are fuzzy terms that cannot be described by classical mathematics but can be quantified by membership functions (see Fig. 2, where part (a) is an example of the description “to the left”). The collection of all such “if ... then ...” principles constitutes a *fuzzy logic rule base* for the problem under investigation. To this end, it is helpful to briefly summarize the experience of the driver in the following simplified rule base: Let $X = [-180^\circ, 180^\circ]$, x be the position of the car, $\mu_{left}(\cdot)$ be the membership function for the moving car turning “to the left,” $\mu_{right}(\cdot)$ the membership function for the car turning “to the right,” and $\mu_0(\cdot)$ the membership function for the car “moving straight ahead.” Here, simplified statements are used, for instance, “ x is X_{left} ” means “ x belongs to X with a membership value $\mu_{left}(x)$ ” etc. Also, similar notation for the control action u of the driver is employed. Then, a simple typical rule base for this car-driving task is

| | | |
|------------|-----------------------|-------------------------|
| $R^{(1)}:$ | IF x is X_{left} | THEN u is U_{right} |
| $R^{(2)}:$ | IF x is X_{right} | THEN u is U_{left} |
| $R^{(3)}:$ | IF x is X_0 | THEN u is U_0 |

where X_0 means moving straight ahead (not left nor right), as described by the membership function shown in Fig. 2(c), and “ u is U_0 ” means $u = 0$ (no control action) with a certain grade (if this grade is 1, it means absolutely no control action). Of course, this description only illustrates the basic idea, which is by no means a complete and effective design for a real car-driving application.

In general, a rule base of r rules has the form

$$R^{(k)}: \text{IF } x_1 \text{ is } X_{k1} \text{ AND } \cdots \text{ AND } x_m \text{ is } X_{km} \text{ THEN } u \text{ is } U_k \quad (1)$$

where $m \geq 1$ and $k = 1, \dots, r$.

Defuzzification

An element of a fuzzy set may have more than one membership value. In Fig. 1, for instance, if $x = 5^\circ$ then it has two membership values: $\mu_{\text{right}}(x) = 5/180 \approx 0.28$ and $\mu_0(x) = 0.5$. This means that the car is moving to the right by a little. According to the above-specified rule base, the driver will take two control actions simultaneously, which is unnecessary and physically impossible.

Thus, what should the control action be? To simplify this discussion, suppose that the control action is simply $u = -x$ with the same membership functions $\mu_x = \mu_u$ for all cases. Then, a natural and realistic control action for the driver to take is a compromise between the two required actions. Among several possible compromise (or, average) formulas for this purpose, the most commonly adopted one that works well in most cases is the following weighted average formula:

$$u = \frac{\mu_{\text{right}}(u) \cdot u + \mu_0(u) \cdot u}{\mu_{\text{right}}(u) + \mu_0(u)} = \frac{0.28 \times (-5^\circ) + 0.5 \times (-5^\circ)}{0.28 + 0.5} = -0.5^\circ$$

Here, the result is interpreted as “the driver should turn the car to the left by 5° .” This averaged outputs is called *defuzzification*, which yields a single crisp value for the control, which may actually yield similar averaged results in general.

The result of defuzzification usually is a physical quantity acceptable by the original real system. Whether or not this defuzzification result works well depends

Figure 1. Membership functions for directions of a moving car

Figure 2. A typical fuzzy logic controller

on the correctness and effectiveness of the rule base, while the latter depends on the designer's knowledge and experience about the physical system or process for control. Just like any of the classical design problems, there is generally no unique solution for a problem; an experienced designer usually comes out with a better design.

A general weighted average formula for defuzzification is the following convex combination of the individual outputs:

$$output = \sum_{i=1}^r \alpha_i u_i := \sum_{i=1}^r \frac{w_i}{\sum_{i=1}^r w_i} \cdot u_i \quad (2)$$

with notation referred to the rule base (1), where

$$w_i \mu_{U_i}(u_i), \quad \alpha_i := \frac{w_i}{\sum_{i=1}^r w_i} \geq 0, \quad i = 1, \dots, r, \quad \sum_{i=1}^r \alpha_i = 1$$

Sometimes, depending on the design or application, the weights are

$$w_i = \prod_{j=1}^m \mu_{X_{ij}}(x_j), \quad i = 1, \dots, r$$

The overall structure of a fuzzy logic controller is shown in Fig. 2.

MAIN FOCUS OF THE CHAPTER: SOME BASIC FUZZY CONTROL APPROACHES

A Model-Free Approach

This general approach of fuzzy logic control works for trajectory tracking for a conventional dynamical system that does not have a precise mathematical model.

The basic setup is shown in Fig. 3, where the plant is a conventional system without a mathematical description and all the signals (the reference set-point sp , output $y(t)$, control $u(t)$, and error $e(t) = sp - y(t)$) are crisp. The objective is to design a controller to achieve the goal $e(t) \rightarrow 0$ as $t \rightarrow \infty$, assuming that the system inputs and outputs are measurable by sensors on line.

If the mathematical formulation of the plant is unknown, how can one develop a controller to control this plant? Fuzzy logic approach turns out to be advantageous in this situation: it only uses the plant inputs and outputs, but not the state variables nor any other information. After the design is completed, the entire dashed-block in Fig. 2 is used to replace the “controller” block in Fig. 3.

As an example, suppose that the physical reference set-point is the degree of temperature, say $40^\circ F$, and that the designer knows the range of the error signal, $e(t) = 40^\circ - y(t)$, is within $X = [-25^\circ, 45^\circ]$, and assume that the scale of control is required to be in the unit of 1° . Then, the membership functions for the error signal to be “negative large” (NL), “positive large” (PL), and “zero” (ZO) may be chosen as shown in Fig.

Figure 3. A typical reference set-point tracking control system

4. Using these membership functions, the controller is expected to drive the output temperature to be within the allowable range: $40^\circ \pm 1^\circ$. With these membership functions, when the error signal $e(t) = 5^\circ$, for instance,

Figure 4. Membership function for the error temperature signal

it is considered to be “positive large” with membership value one, meaning that the set-point (40°) is higher than $y(t)$ by too much.

The output from the fuzzification module is a fuzzy set consisting of the interval X and three membership functions, μ_{NL} , μ_{PL} and μ_{ZO} , in this example. The output from fuzzification will be the input to the next module—the fuzzy logic rule base—which only takes fuzzy set inputs to be compatible with the logical IF-THEN rules.

Figure 5 is helpful for establishing the rule base. If $e > 0$ at a moment, then the set-point is higher than the output y (since $e = 40^\circ - y$), which corresponds to two possible situations, marked by a and d respectively. To further distinguish these two situations, one may use the rate of change of the error, $\dot{e} = -\dot{y}$. Here, since the set-point is a constant, its derivative is zero. Using information from both e and \dot{e} , one can completely characterize the changing situation of the output temperature at all times. If, for example, $e > 0$ and $\dot{e} > 0$,

Figure 5. Temperature set-point tracking example

then the temperature is currently at situation d rather than situation a , since $\dot{e} > 0$ means $\dot{y} < 0$ which, in turn, signifies that the curve is moving downward.

Based on the above observation from the physical situations of the current temperature against the set-point, a simple rule base can be established as follows:

- R^1 : IF $e > 0$ AND $\dot{e} > 0$ THEN $u(t+) = -C \cdot u(t)$;
 R^2 : IF $e > 0$ AND $\dot{e} < 0$ THEN $u(t+) = C \cdot u(t)$;
 R^3 : IF $e < 0$ AND $\dot{e} > 0$ THEN $u(t+) = C \cdot u(t)$;
 R^4 : IF $e < 0$ AND $\dot{e} < 0$ THEN $u(t+) = -C \cdot u(t)$;

otherwise (e.g., $e = 0$ or $\dot{e} = 0$), $u(t+) = u(t)$, till next step, where $C > 0$ is a constant control gain and $t+$ can be just $t + 1$ in discrete time.

In the above, the first two rules are understood as follows (other rules can be similarly interpreted):

1. $R^{(1)}$: $e > 0$ and $\dot{e} > 0$. As analyzed above, the temperature curve is currently at situation d , so the controller has to change its moving direction to the opposite by changing the current control action to the opposite (since the current control action is driving the output curve downward).
2. $R^{(2)}$: $e > 0$ and $\dot{e} < 0$. The current temperature curve is at situation a , so the controller does not need to do anything (since the current control action is driving the output curve up toward the set-point).

The switching control actions may take different forms, depending on the design. One example is $u(t + 1) = u(t) + \Delta u(t)$, among others (Chen & Pham, 1999, 2006).

Furthermore, to distinguish “positive large” from just “positive” for $e > 0$, one may use those membership functions shown in Fig. 4. Since the error signal $e(t)$ is fuzzified in the fuzzification module, one can similarly fuzzify the auxiliary signal $\dot{e}(t)$ in the fuzzification module. Thus, there are two fuzzified inputs, e and \dot{e} , for the controller, and they both have corresponding membership functions describing their properties as “positive large” (μ_{PL}), “negative large” (μ_{NL}), or “zero” (μ_{ZO}), as shown in Fig. 5. Thus, for the rule base, one may replace it by a set of more detailed rules as follows:

- R^1 : IF $e = PL$ AND $\dot{e} > 0$ THEN $u(t+1) = -\mu_{PL}(e) \cdot u(t)$;
 R^2 : IF $e = PS$ AND $\dot{e} > 0$ THEN $u(t+1) = -(1-\mu_{PS}(e)) \cdot u(t)$;
 R^3 : IF $e = PL$ AND $\dot{e} < 0$ THEN $u(t+1) = \mu_{PL}(e) \cdot u(t)$;
 R^4 : IF $e = PS$ AND $\dot{e} < 0$ THEN $u(t+1) = (1-\mu_{PS}(e)) \cdot u(t)$;
 R^5 : IF $e = NL$ AND $\dot{e} > 0$ THEN $u(t+1) = \mu_{NL}(e) \cdot u(t)$;
 R^6 : IF $e = NS$ AND $\dot{e} > 0$ THEN $u(t+1) = (1-\mu_{NS}(e)) \cdot u(t)$;
 R^7 : IF $e = NL$ AND $\dot{e} < 0$ THEN $u(t+1) = -\mu_{NL}(e) \cdot u(t)$;
 R^8 : IF $e = NS$ AND $\dot{e} < 0$ THEN $u(t+1) = -(1-\mu_{NS}(e)) \cdot u(t)$;

otherwise, $u(t+1) = u(t)$. Here and below, “= PL” means “is PL,” etc. In this way, the initial rule base is enhanced and extended.

In the defuzzification module, new membership functions are needed for the change of the control action, $u(t + 1)$ or $\Delta u(t)$, if the enhanced rule base described above is used. This is because both the error and the rate of change of the error signals have been fuzzified to be “positive large” or “positive small,” the control actions have to be fuzzified accordingly (to be “large” or “small”).

Now, suppose that a complete, enhanced fuzzy logic rule base has been established. Then, in the defuzzification module, the weighted average formula can be used to obtain a single crisp value as the control action output from the controller (see Fig. 2):

$$u(t + 1) = \frac{\sum_{i=1}^N \mu_i \cdot u_i(t + 1)}{\sum_{i=1}^N \mu_i}$$

This is an average value of the multiple ($N = 8$ in the above rule base) control signals at step $t + 1$, and is physically meaningful to the given plant.

A Model-Based Approach

If a mathematical model of the system, or a fairly good approximation of it, is available, one may be able to design a fuzzy logic controller with better results such as performance specifications and guaranteed stability.

This constitutes a model-based fuzzy control approach (Chen & Zhang, 1997; Malki, Li & Chen, 1994; Malki, Feigenspan, Misir & Chen, 1997; Sooraksa & Chen, 1998; Ying, Siler & Buckley, 1990).

For instance, a locally linear fuzzy system model is described by a rule base of the following form:

$$\begin{aligned} R_S^{(k)} : & \text{IF } x_1 \text{ is } X_{k1} \quad \text{AND} \quad \dots \\ & \text{AND } x_m \text{ is } X_{km} \quad \text{THEN } \dot{\underline{x}} = A_k \underline{x} + B_k \underline{u} \end{aligned} \quad (3)$$

where $\{A_k\}$ and $\{B_k\}$ are given constant matrices, $\underline{x} = [x_1, \dots, x_m]^T$ is the state vector, and $\underline{u} = [u_1, \dots, u_n]^T$ is a controller to be designed, with $m \geq n \geq 1$, and $k = 1, \dots, r$. The fuzzy system model (3) may be rewritten in a more compact form as follows:

$$\dot{\underline{x}} = \sum_{k=1}^r \alpha_k (A_k \underline{x} + B_k \underline{u}) = A(\mu(\underline{x})) \underline{x} + B(\mu(\underline{x})) \underline{u} \quad (4)$$

where

$$\mu(\underline{x}) = \left\{ \mu_{x_{ij}}(\underline{x}) \right\}_{i,j=1}^m.$$

Based on this fuzzy model, (3) or (4), a fuzzy controller $\underline{u}(t)$ can be designed by using some conventional techniques. For example, if a negative state-feedback controller is preferred, then one may design a controller described by the following rule base:

$$\begin{aligned} R_C^{(k)} : & \text{IF } x_1 \text{ is } X_{k1} \quad \text{AND} \quad \dots \\ & \text{AND } x_m \text{ is } X_{km} \quad \text{THEN } \underline{u} = -K_k \underline{x} \end{aligned} \quad (5)$$

where $\{K_k\}_{k=1}^r$ are constant control gain matrices to be determined, $k = 1, \dots, r$. Thus, the closed-loop controlled system (4) together with (5) becomes

$$\begin{aligned} R_{SC}^{(k)} : & \text{IF } x_1 \text{ is } X_{k1} \quad \text{AND} \quad \dots \\ & \text{AND } x_m \text{ is } X_{km} \quad \text{THEN } \dot{\underline{x}} = [A_k - BK_k] \underline{x} \end{aligned} \quad (6)$$

For this feedback controlled system, the following is a typical stability condition [1,2,10]:

If there exists a common positive definite and symmetric constant matrix P such that $A_k^T P + P A_k = -Q$ for some

$Q > 0$ for all $k = 1, \dots, r$, then the fuzzy controlled system (6) is asymptotically stable about zero.

This theorem provides a basic (sufficient) condition for the global asymptotic stability of the fuzzy control system, which can also be viewed as a criterion for tracking control of the system trajectory to the zero set-point. Clearly, stable control gain matrices $\{K_k\}_{k=1}^r$ may be determined according to this criterion in a design.

FUTURE TRENDS

This topic will be discussed elsewhere in the near future.

CONCLUSION

The essence of systems control is to achieve automation. For this purpose, a combination of fuzzy control technology and advanced computer facility available in the industry provides a promising approach that can mimic human thinking and linguistic control ability, so as to equip the control systems with a certain degree of artificial intelligence. It has now been realized that fuzzy control systems theory offers a simple, realistic and successful addition, or sometimes an alternative, for controlling various complex, imperfectly modeled, and highly uncertain engineering systems, with a great potential in many real-world applications.

KEY TERMS

Defuzzification: A process that converts fuzzy terms to conventional expressions quantified by real-valued functions.

Fuzzification: A process that converts conventional expressions to fuzzy terms quantified by fuzzy membership functions.

Fuzzy Control: A control method based on fuzzy set and fuzzy logic theories.

Fuzzy Logic: A logic that takes on continuous values in between 0 and 1.

Fuzzy Membership Function: A function defined on fuzzy set and assumes continuous values in between 0 and 1.

Fuzzy Set: A set of elements with a real-valued membership function describing their grades.

Fuzzy System: A system formulated and described by fuzzy set-based real-valued functions.

Fuzzy Decision Trees

Malcolm J. Beynon
Cardiff University, UK

INTRODUCTION

The inductive learning methodology known as decision trees, concerns the ability to classify objects based on their attributes values, using a tree like structure from which decision rules can be accrued. In this article, a description of decision trees is given, with the main emphasis on their operation in a fuzzy environment.

A first reference to decision trees is made in Hunt *et al.* (1966), who proposed the Concept learning system to construct a decision tree that attempts to minimize the score of classifying chess endgames. The example problem concerning chess offers early evidence supporting the view that decision trees are closely associated with artificial intelligence (AI). It is over ten years later that Quinlan (1979) developed the early work on decision trees, to introduced the Interactive Dichotomizer 3 (ID3). The important feature with their development was the use of an entropy measure to aid the decision tree construction process (using again the chess game as the considered problem).

It is ID3, and techniques like it, that defines the hierarchical structure commonly associated with decision trees, see for example the recent theoretical and application studies of Pal and Chakraborty (2001), Bhatt and Gopal (2005) and Armand *et al.* (2007). Moreover, starting from an identified root node, paths are constructed down to leaf nodes, where the attributes associated with the intermediate nodes are identified through the use of an entropy measure to preferentially gauge the classification certainty down that path. Each path down to a leaf node forms an 'if .. then ..' decision rule used to classify the objects.

The introduction of fuzzy set theory in Zadeh (1965), offered a general methodology that allows notions of vagueness and imprecision to be considered. Moreover, Zadeh's work allowed the possibility for previously defined techniques to be considered with a fuzzy environment. It was over ten years later that the area of decision trees benefited from this fuzzy environment opportunity (see Chang and Pavlidis, 1977). Since then there has been a steady stream of research

studies that have developed or applied fuzzy decision trees (FDTs) (see recently for example Li *et al.*, 2006 and Wang *et al.*, 2007).

The expectations that come with the utilisation of FDTs are succinctly stated by Li *et al.* (2006, p. 655);

"Decision trees based on fuzzy set theory combines the advantages of good comprehensibility of decision trees and the ability of fuzzy representation to deal with inexact and uncertain information."

Chiang and Hsu (2002) highlight that decision trees has been successfully applied to problems in artificial intelligence, pattern recognition and statistics. They go onto outline a positive development the FDTs offer, namely that it is better placed to have an estimate of the degree that an object is associated with each class, often desirable in areas like medical diagnosis (see Quinlan (1987) for the alternative view with respect to crisp decision trees).

The remains of this article look in more details at FDTs, including a tutorial example showing the rudiments of how an FDT can be constructed.

BACKGROUND

The background section of this article concentrates on a brief description of fuzzy set theory pertinent to FDTs, followed by a presentation of one FDT technique.

In fuzzy set theory (Zadeh, 1965), the grade of membership of a value x to a set S is defined through a membership function $\mu_s(x)$ that can take a value in the range $[0, 1]$. The accompanying numerical attribute domain can be described by a finite series of MFs that each offers a grade of membership to describe x , which collectively form its concomitant fuzzy number. In this article, MFs are used to formulate linguistic variables for the considered attributes. These linguistic variables are made up of sets of linguistic terms which are defined by the MFs (see later).

Figure 1. Example membership function and their use in a linguistic variable

Surrounding the notion of MFs is the issue of their structure (Dombi and Gera, 2005). Here, piecewise linear MFs are used to define the linguistic terms presented, see Figure 1.

In Figure 1(top), a single piecewise linear MF is shown along with the defining values that define it, namely, $\alpha_{1,1}$, $\alpha_{1,2}$, $\alpha_{1,3}$, $\alpha_{1,4}$ and $\alpha_{1,5}$. The associated mathematical structure of this specific form of MF is given below;

$$\mu(x) = \begin{cases} 0 & \text{if } x \leq \alpha_{j,1} \\ 0.5 \frac{x - \alpha_{j,1}}{\alpha_{j,2} - \alpha_{j,1}} & \text{if } \alpha_{j,1} < x \leq \alpha_{j,2} \\ 0.5 + 0.5 \frac{x - \alpha_{j,2}}{\alpha_{j,3} - \alpha_{j,2}} & \text{if } \alpha_{j,2} < x \leq \alpha_{j,3} \\ 1 & \text{if } x = \alpha_{j,3} \\ 1 - 0.5 \frac{x - \alpha_{j,3}}{\alpha_{j,4} - \alpha_{j,3}} & \text{if } \alpha_{j,3} < x \leq \alpha_{j,4} \\ 0.5 - 0.5 \frac{x - \alpha_{j,4}}{\alpha_{j,5} - \alpha_{j,4}} & \text{if } \alpha_{j,4} < x \leq \alpha_{j,5} \\ 0 & \text{if } \alpha_{j,5} < x \end{cases}$$

As mentioned earlier, MFs of this type are used to define the linguistic terms which make up linguistic variables. An example of a linguistic variable X based on two linguistic terms, X1 and X2, is shown in Figure 2(bottom), where the overlap of the defining values for

each linguistic term is evident. Moreover, using left and right limits of the X domain as $-\infty$ and ∞ , respectively, the sets of defining values are (in list form); X1 - $[-\infty, -\infty, \alpha_{1,3}, \alpha_{1,4}, \alpha_{1,5}]$ and X2 - $[\alpha_{2,1}, \alpha_{2,2}, \alpha_{2,3}, \infty, \infty]$, where $\alpha_{1,3} = \alpha_{2,1}$, $\alpha_{1,4} = \alpha_{2,2}$ and $\alpha_{1,5} = \alpha_{2,3}$.

This section now goes on to outline the technical details of the fuzzy decision tree approach introduced in Yuan and Shaw (1995). With an inductive fuzzy decision tree, the underlying knowledge related to a decision outcome can be represented as a set of fuzzy ‘if .. then ..’ decision rules, each of the form;

If (A_1 is $T_{i_1}^1$) and (A_2 is $T_{i_2}^2$) ... and (A_k is $T_{i_k}^k$) then C is C_j , where A_1, A_2, \dots, A_k and C are linguistic variables for the multiple antecedents (A_i 's) and consequent (C) statements used to describe the considered objects, and $T(A_k) = \{T_1^k, T_2^k, \dots, T_{S_i}^k\}$ and $\{C_1, C_2, \dots, C_L\}$ are their respective linguistic terms, defined by the MFs $\mu_{T_j^k}(x)$ etc. The MFs, $\mu_{T_j^k}(x)$ and $\mu_{C_j}(y)$, represent the grade of membership of an object's antecedent A_j being T_j^k and consequent C being C_j , respectively.

A MF $\mu(x)$ from the set describing a fuzzy linguistic variable Y defined on X, can be viewed as a possibility distribution of Y on X, that is $\pi(x) = \mu(x)$, for all $x \in X$ the values taken by the objects in U (also normalized so $\max_{x \in X} \pi(x) = 1$). The possibility measure $E_\alpha(Y)$ of ambiguity is defined by

$$E_\alpha(Y) = g(\pi) = \sum_{i=1}^n (\pi_i^* - \pi_{i+1}^*) \ln[i],$$

where $\pi^* = \{\pi_1^*, \pi_2^*, \dots, \pi_n^*\}$ is the permutation of the normalized possibility distribution $\pi = \{\pi(x_1), \pi(x_2), \dots, \pi(x_n)\}$, sorted so that $\pi_i^* \geq \pi_{i+1}^*$ for $i = 1, \dots, n$, and $\pi_{n+1}^* = 0$.

The ambiguity of attribute A (over the objects u_1, \dots, u_m) is given as:

$$E_\alpha(A) = \frac{1}{m} \sum_{i=1}^m E_a(A(u_i)),$$

where

$$E_\alpha(A(u_i)) = g(\mu_{T_s}(u_i) / \max_{1 \leq j \leq s} (\mu_{T_j}(u_i))),$$

with T_1, \dots, T_s the linguistic terms of an attribute (antecedent) with m objects.

The fuzzy subsethood $S(A, B)$ measures the degree to which A is a subset of B , and is given by,

$$S(A, B) = \sum_{u \in U} \min(\mu_A(u), \mu_B(u)) / \sum_{u \in U} \mu_A(u).$$

Given fuzzy evidence E , the possibility of classifying an object to the consequent C_i can be defined as,

$$\pi(C_i/E) = S(E, C_i) / \max_j S(E, C_j),$$

where the fuzzy subsethood $S(E, C_i)$ represents the degree of truth for the classification rule ('if E then C_i '). With a single piece of evidence (a fuzzy number for an attribute), then the classification ambiguity based on this fuzzy evidence is defined as: $G(E) = g(\pi(C|E))$, which is measured using the possibility distribution $\pi(C|E) = (\pi(C_1|E), \dots, \pi(C_L|E))$.

The classification ambiguity with fuzzy partitioning $P = \{E_1, \dots, E_k\}$ on the fuzzy evidence F , denoted as $G(P|F)$, is the weighted average of classification ambiguity with each subset of partition:

$$G(P|F) = \sum_{i=1}^k w(E_i|F) G(E_i \cap F),$$

where $G(E_i \cap F)$ is the classification ambiguity with fuzzy evidence $E_i \cap F$, and where $w(E_i|F)$ is the weight which represents the relative size of subset $E_i \cap F$ in

$$F: w(E_i|F) =$$

$$\sum_{u \in U} \min(\mu_{E_i}(u), \mu_F(u)) / \sum_{j=1}^k \left(\sum_{u \in U} \min(\mu_{E_j}(u), \mu_F(u)) \right)$$

In summary, attributes are assigned to nodes based on the lowest level of classification ambiguity. A node becomes a leaf node if the level of subsethood is higher than some truth value β assigned to the whole of the fuzzy decision tree. The classification from the leaf node is to the decision group with the largest subsethood value. The truth level threshold β controls the growth of the tree; lower β may lead to a smaller tree (with lower classification accuracy), higher β may lead to a larger tree (with higher classification accuracy).

MAIN THRUST

The main thrust of this article is a detailed example of the construction of a fuzzy decision tree. The description includes the transformation of a small data set into a fuzzy data set where the original values are described by their degrees of membership to certain linguistic terms.

The small data set considered, consists of five objects, described by three condition attributes T1, T2 and T3, and classified by a single decision attribute C, see Table 1.

If these values are considered imprecise, fuzzy, there is the option to transform the data values in

Table 1. Example data set

| Object | T1 | T2 | T3 | C |
|--------|-----|----|-----|----|
| u_1 | 112 | 45 | 205 | 7 |
| u_2 | 85 | 42 | 192 | 17 |
| u_3 | 130 | 58 | 188 | 22 |
| u_4 | 93 | 54 | 203 | 29 |
| u_5 | 132 | 39 | 189 | 39 |

Figure 2. Membership functions defining the linguistic terms, C_L and C_H , for the decision attribute C

fuzzy values. Here, an attribute is transformed into a linguistic variable, each described by two linguistic terms, see Figure 2.

In Figure 2, the decision attribute C is shown to be described by the linguistic terms, C_L and C_H (possibly denoting the terms low and high). These linguistic terms are themselves defined by MFs ($\mu_{C_L}(\cdot)$ and $\mu_{C_H}(\cdot)$). The hypothetical MFs shown have the respective defining terms of, $\mu_{C_L}(\cdot)$: $[-\infty, -\infty, 9, 25, 32]$ and $\mu_{C_H}(\cdot)$: $[9, 25,$

$32, \infty, \infty]$. To demonstrate their utilisation, for the object u_2 , with a value $C = 17$, its fuzzification creates the two values $\mu_{C_L}(17) = 0.750$ and $\mu_{C_H}(17) = 0.250$, the larger of which is associated with the high linguistic term.

A similar series of membership functions can be constructed for the three condition attributes, T1, T2 and T3, Figure 3.

In Figure 3, the linguistic variable version of each condition attribute is described by two linguistic terms

Figure 3. Membership functions defining the linguistic terms for the condition attributes, T1, T2 and T3

Table 2. Fuzzified version of the example data set

| Object | T1 = [T1 _L , T1 _H] | T2 = [T2 _L , T2 _H] | T3 = [T3 _L , T3 _H] | C = [C _L , C _H] |
|--------|---|---|---|--|
| o_1 | [0.433, 0.567] - H | [1.000 , 0.000] - L | [0.000, 1.000] - H | [1.000 , 0.000] - L |
| o_2 | [1.000 , 0.000] - L | [1.000 , 0.000] - L | [0.750 , 0.250] - L | [0.750 , 0.250] - L |
| o_3 | [0.000, 1.000] - H | [0.227, 0.773] - H | [0.917 , 0.083] - L | [0.594 , 0.406] - L |
| o_4 | [1.000 , 0.000] - L | [0.409, 0.591] - H | [0.000, 1.000] - H | [0.214, 0.786] - H |
| o_5 | [0.000, 1.000] - H | [1.000 , 0.000] - L | [0.875 , 0.125] - L | [0.000, 1.000] - H |

(possibly termed as low and high), themselves defined by MFs. The use of these series of MFs is the ability to fuzzify the example data set, see Table 2.

In Table 2, each object is described by a series of fuzzy values, two fuzzy values for each attribute. Also shown in Table 2, in bold, are the larger of the values in each pair of fuzzy values, with the respective linguistic term this larger value is associated with. Beyond the fuzzification of the data set, attention turns to the construction of the concomitant fuzzy decision tree for this data. Prior to this construction process, a threshold value of $\beta = 0.75$ for the minimum required truth level was used throughout.

The construction process starts with the condition attribute that is the root node. For this, it is necessary to calculate the classification ambiguity $G(E)$ of each condition attribute. The evaluation of a $G(E)$ value is shown for the first attribute T1 (i.e. $g(\pi(C|T1))$), where it is broken down to the fuzzy labels L and H, for L;

$$\pi(C|T1_L) = S(T1_L, C_L) / \max_j S(T1_L, C_j),$$

considering C_L and C_H with the information in Table 1;

$$S(T1_L, C_L) = \sum_{u \in U} \min(\mu_{T1_L}(u), \mu_{C_L}(u)) / \sum_{u \in U} \mu_{T1_L}(u) = 1.398/2.433 = 0.574,$$

whereas, $S(T1_L, C_H) = 0.426$. Hence $\pi = \{0.574, 0.426\}$, giving the ordered normalized form of $\pi^* = \{1.000, 0.741\}$, with $p_3^* = 0$, then

$$G(T1_L) = g(\pi(C|T1_L)) = \sum_{i=1}^2 (\pi_i^* - \pi_{i+1}^*) \ln[i] = 0.514,$$

along with $G(T1_H) = 0.572$, then $G(T1) = (0.514 + 0.572)/2 = 0.543$. Compared with $G(T2) = 0.579$ and $G(T3) = 0.583$, the condition attribute T1, with the least classification ambiguity, forms the root node for the desired fuzzy decision tree.

The subethood values in this case are; for T1: $S(T1_L, C_L) = \mathbf{0.574}$ and $S(T1_L, C_H) = \mathbf{0.426}$, and $S(T2_H, C_L) = 0.452$ and $S(T2_H, C_H) = \mathbf{0.548}$. For $T2_L$ and $T2_H$, the larger subethood value (in bold), defines the possible classification for that path. In both cases these values are less than the threshold truth value 0.75 employed, so neither of these paths can be terminated to a leaf node, instead further augmentation of them is considered.

With three condition attributes included in the example data set, the possible augmentation to $T1_L$ is with either T2 or T3. Concentrating on T2, where with $G(T1_L) = 0.514$, the ambiguity with partition evaluated for T2 ($G(T1_L \text{ and } T2|C)$) has to be less than this value, where;

$$G(T1_L \text{ and } T2|C) = \sum_{i=1}^k w(T2_i | T1_L) G(T1_L \cap T2_i).$$

Starting with the weight values, in the case of $T1_L$ and $T2_L$, it follows;

$$w(T2_L | T1_L) =$$

$$\sum_{u \in U} \min(\mu_{T2_L}(u), \mu_{T1_L}(u)) / \sum_{j=1}^k \left(\sum_{u \in U} \min(\mu_{T2_j}(u), \mu_{T1_L}(u)) \right) =$$

$$1.842/2.433 = 0.757.$$

Similarly $w(T2_H | T1_L) = 0.243$, hence;

$$G(T1_L \text{ and } T2 | C) = 0.757 \times G(T1_L \cap T2_L) + 0.699 \times G(T1_L \cap T2_H) = 0.757 \times 0.327 + 0.699 \times 0.251 = 0.309,$$

A concomitant value for $G(T1_L \text{ and } T3 | C) = 0.487$, the lower of these ($G(T1_L \text{ and } T2 | C)$) is lower than the concomitant $G(T1_L) = 0.514$, so less ambiguity would be found if the T2 attribute was augmented to the path $T1 = L$. The subsequent subsethood values in this case for each new path are; $T2_L: S(T1_L \cap T2_L, C_L) = \mathbf{0.759}$ and $S(T1_L \cap T2_L, C_H) = \mathbf{0.358}$; $T2_H: S(T1_L \cap T2_H, C_L) = 0.363$ and $S(T1_L \cap T2_H, C_H) = \mathbf{1.000}$. With each suggested classification path, the largest subsethood value is above the truth level threshold, therefore they are both leaf nodes leading from the $T1 = L$ path. The construction process continues in a similar vein for the path $T1 = H$, with the resultant fuzzy decision tree in this case presented in Figure 4.

The fuzzy decision tree in Figure 8 shows five rules (leaf nodes), **R1**, **R2**, ..., **R5**, have been constructed. There are a maximum of four levels to the tree shown, indicating a maximum of three condition attributes are used in the rules constructed. In each non-root node shown the subsethood levels to the decision attribute terms $C = L$ and $C = H$ are shown. On the occasions when the larger of the subsethood values is above the

defined threshold value of 0.75 then they are shown in bold and accompany the node becoming a leaf node.

The interpretative power of FDTs is shown by consideration of the rules constructed. For the rule R5 it can be written down as;

‘If $T1 = H$ and $T3 = H$ then $C = L$ with truth level 0.839.’

The rules can be considered in a more linguistic form, namely;

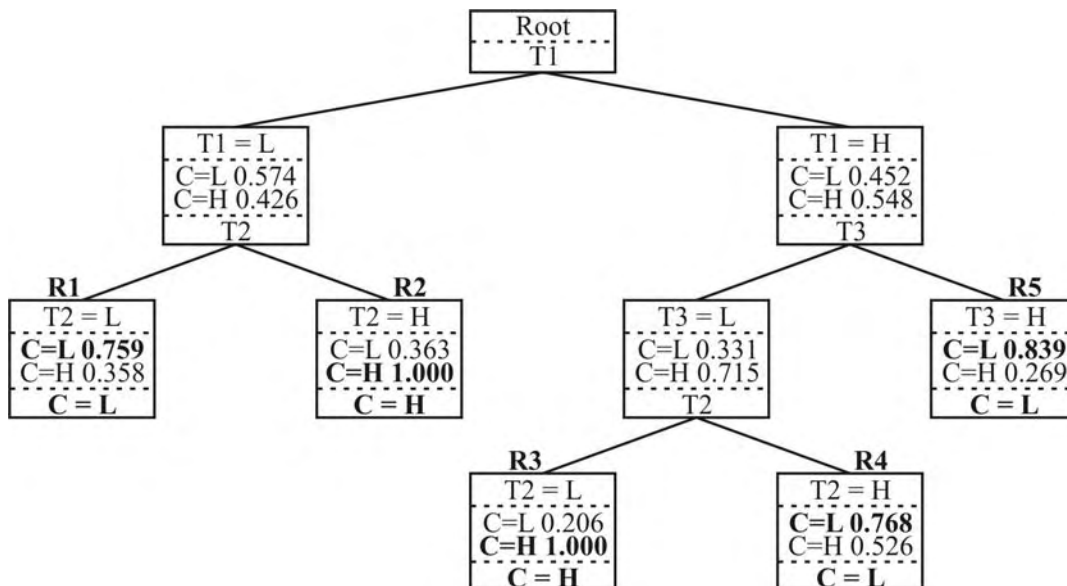

‘If T1 is low and T3 is high then C is low with truth level 0.839.’

It is the rules like this one shown that allow the clearest interpretability to the understanding of results in classification problems when using FDTs.

FUTURE TRENDS

Fuzzy decision trees (FDTs) benefit from the inductive learning approach that underpins their construction, to aid in the classification of objects based on their values over different attribute. Their construction in a fuzzy

Figure 4. Fuzzy decision tree for example data set

environment allows for the potential critical effects of imprecision to be mitigated, as well as brings a beneficial level of interpretability to the results found, through the decision rules defined.

As with the more traditional ‘crisp’ decision tree approaches, there are issues such as the complexity of the results, in this case the tree defined. Future trends will surely include how FDTs can work on re-grading the complexity of the tree constructed, commonly known as pruning. Further, the applicability of the rules constructed, should see the use of FDTs extending in the range of applications it can work with.

CONCLUSION

The interest in FDTs, with respect to AI, is due to the inductive learning and linguistic rule construction processes that are inherent with it. The induction undertaken, truly lets the analysis create intelligent results from the data available. Many of the applications FDTs have been used within, such medicine, have benefited greatly from the interpretative power of the readable rules. The accessibility of the results from FDTs should secure it a positive future.

KEY TERMS

Condition Attribute: An attribute that describes an object. Within a decision tree it is part of a non-leaf node, so performs as an antecedent in the decision rules used for the final classification of an object.

Decision Attribute: An attribute that characterises an object. Within a decision tree is part of a leaf node, so performs as a consequent, in the decision rules, from the paths down the tree to the leaf node.

Decision Tree: A tree-like structure for representing a collection of hierarchical decision rules that lead to a class or value, starting from a root node ending in a series of leaf nodes.

Induction: A technique that infers generalizations from the information in the data.

Leaf Node: A node not further split, the terminal grouping, in a classification or decision tree.

Linguistic Term: One of a set of linguistic terms, which are subjective categories for a linguistic variable, each described by a membership function.

Linguistic Variable: A variable made up of a number of words (linguistic terms) with associated degrees of membership.

Path: A path down the tree from root node to leaf node, also termed a branch.

Membership Function: A function that quantifies the grade of membership of a variable to a linguistic term.

Node: A junction point down a path in a decision tree that describes a condition in an if-then decision rule. From a node, the current path may separate into two or more paths.

Root Node: The node at the top of a decision tree, from which all paths originate and lead to a leaf node.

Fuzzy Graphs and Fuzzy Hypergraphs

Leonid S. Bershtein

Taganrog Technological Institute of Southern Federal University, Russia

Alexander V. Bozhenyuk

Taganrog Technological Institute of Southern Federal University, Russia

INTRODUCTION

Graph theory has numerous application to problems in systems analysis, operations research, economics, and transportation. However, in many cases, some aspects of a graph-theoretic problem may be uncertain. For example, the vehicle travel time or vehicle capacity on a road network may not be known exactly. In such cases, it is natural to deal with the uncertainty using the methods of fuzzy sets and fuzzy logic.

Hypergraphs (Berge, 1989) are the generalization of graphs in case of set of multiarity relations. It means the expansion of graph models for the modeling complex systems. In case of modelling systems with fuzzy binary and multiarity relations between objects, transition to fuzzy hypergraphs, which combine advantages both fuzzy and graph models, is more natural. It allows to realise formal optimisation and logical procedures.

However, using of the fuzzy graphs and hypergraphs as the models of various systems (social, economic systems, communication networks and others) leads to difficulties. The graph isomorphic transformations are reduced to redefinition of vertices and edges. This redefinition doesn't change properties the graph determined by an adjacent and an incidence of its vertices and edges.

Fuzzy independent set, domination fuzzy set, fuzzy chromatic set are invariants concerning the isomorphism transformations of the fuzzy graphs and fuzzy hypergraph and allow make theirs structural analysis.

BACKGROUND

The idea of fuzzy graphs has been introduced by Rosenfeld in a paper in (Zadeh, 1975), which has also been discussed in (Kaufmann, 1977).

The questions of using fuzzy graphs for cluster analysis were considered in (Matula, 1970, Matula, 1972). The

questions of using fuzzy graphs in Database Theory were discussed in (Kiss, 1991). The tasks of allocations centers on fuzzy graphs were considered in (Moreno, Moreno & Verdegay, 2001, Kutangila-Mayoya & Verdegay, 2005, Rozenberg & Starostina, 2005). The analyses and research of flows and vitality in transportation nets were considered in (Bozhenyuk, Rozenberg & Starostina, 2006). The fuzzy hypergraph applications to portfolio management, managerial decision making, neural cell-assemblies were considered in (Monderson & Nair, 2000). The using of fuzzy hypergraphs for decision making in CAD-Systems were also considered in (Malyshev, Bershtein & Bozhenyuk, 1991).

MAIN DEFINITIONS OF FUZZY GRAPHS AND HYPERGRAPHS

This article presents the main notations of fuzzy graphs and fuzzy hypergraphs, invariants of fuzzy graphs and hypergraphs.

Fuzzy Graph

Let a fuzzy direct graph $\tilde{G} = (X, \tilde{U})$ is given, where X is a set of **vertices**, $\tilde{U} = \{\mu_U(x_i, x_j) | (x_i, x_j) \in X^2\}$ is a fuzzy set of **edges** with the membership function $\mu_U : X^2 \rightarrow [0, 1]$ (Kaufmann, 1977).

Example 1. Let fuzzy graph \tilde{G} has $X = \{x_1, x_2, x_3, x_4\}$, and $\tilde{U} = \{<0.5/(x_1, x_2)>, <0.6/(x_2, x_3)>, <0.3/(x_3, x_4)>, <0.2/(x_4, x_1)>, <1/(x_4, x_2)>\}$. It is presented in figure 1.

The fuzzy graph \tilde{G} may present a fuzzy dependence relation between objects x_1, x_2, x_3 , and x_4 . If the object x_1 fuzzy depends from the object x_i , then there is direct **edge** (x_i, x_1) with membership function $\mu_U(x_i, x_1)$.

If a fuzzy relation, presented by fuzzy graph \tilde{G} , is symmetrical, we have the fuzzy nondirect graph.

Figure 1.

A fuzzy graph $\tilde{G} = (X, \tilde{U})$ is convenient for representing as fuzzy **adjacent matrix** $\|r_{ij}\|_{n \times n}$, where $r_{ij} = \mu_U(x_i, x_j)$. So, the fuzzy graph, presented in figure 1, may be consider by adjacent matrix:

$$R_X = \begin{matrix} & \begin{matrix} x_1 & x_2 & x_3 & x_4 \end{matrix} \\ \begin{matrix} x_1 \\ x_2 \\ x_3 \\ x_4 \end{matrix} & \begin{vmatrix} 0 & 0,5 & 0 & 0 \\ 0 & 0 & 0,6 & 0 \\ 0 & 0 & 0 & 0,3 \\ 0,2 & 1 & 0 & 0 \end{vmatrix} \end{matrix}.$$

The fuzzy graph $\tilde{H} = (X', \tilde{U}')$ is called a fuzzy **subgraph** (Monderson & Nair, 2000) of $\tilde{G} = (X, \tilde{U})$ if $X' \subseteq X$ and $\tilde{U}' \subseteq \tilde{U}$.

Fuzzy directed **path** (Bershtein & Bozhenyuk, 2005) $\tilde{L}(x_i, x_m)$ of graph $\tilde{G} = (X, \tilde{U})$ is called the sequence of fuzzy directed edges from vertex x_i to vertex x_m :

$$\tilde{L}(x_i, x_m) = \langle \mu_U(x_i, x_j) / (x_i, x_j), \mu_U(x_j, x_k) / (x_j, x_k), \dots, \mu_U(x_1, x_m) / (x_1, x_m) \rangle.$$

Conjunctive strength of path $\mu(\tilde{L}(x_i, x_m))$ is defined as:

$$\mu(\tilde{L}(x_i, x_m)) = \bigwedge_{\langle x_a, x_b \rangle \in \tilde{L}(x_i, x_m)} \mu_U(x_a, x_b).$$

Fuzzy directed path $\tilde{L}(x_i, x_m)$ is called simple path between vertices x_i and x_m if its part is not a path between the same vertices.

If a number of vertices $n \geq 3$ and $x_i = x_m$, then the path is called a cycle.

Obviously, what is its definition coincides with the same definition for nonfuzzy graphs.

Vertex y is called fuzzy accessible from vertex x in the graph $\tilde{G} = (X, \tilde{U})$ if exists a fuzzy directed path from vertex x to vertex y .

The accessible degree of vertex y from vertex x , ($x \neq y$) is defined by expression:

$$\gamma(x, y) = \max_{\alpha} (\mu(\tilde{L}_{\alpha}(x, y))), \quad \alpha = 1, 2, \dots, p,$$

where p - number of various simple directed paths from vertex x to vertex y .

A subset of vertices X' is called a fuzzy independent vertex set (Bershtein & Bozhenuk, 2001) with the degree of independence

$$\alpha(X') = 1 - \max_{x_i, x_j \in X'} \{\mu_U(x_i, x_j)\}.$$

A subset of vertices $X' \subseteq X$ of graph \tilde{G} is called a maximal fuzzy independent **vertex** set with the degree $\alpha(X')$, if the condition $\alpha(X'') < \alpha(X')$ is true for any $X' \subset X''$.

Let a set $\tau_k = \{X_{k1}, X_{k2}, \dots, X_{ki}\}$ be given where X_{ki} is a fuzzy independent k -vertex set with the degree of independent α_{ki} . We define as

$$\alpha_k^{max} = \max\{\alpha_{X_{k1}}, \alpha_{X_{k2}}, \dots, \alpha_{X_{ki}}\}.$$

The value α_k^{max} means that fuzzy graph \tilde{G} includes k -vertex subgraph with the degree of independent α_k^{max} and doesn't include k -vertex subgraph with the degree of independence more than α_k^{max} .

A fuzzy set

$$\Psi_X = \{\langle \alpha_1^{max} / 1 \rangle, \langle \alpha_2^{max} / 2 \rangle, \dots, \langle \alpha_n^{max} / n \rangle\}$$

is called a fuzzy **independent set** of fuzzy graph \tilde{G} .

Fuzzy graph \tilde{G} , presented in figure 1, has seven maximum fuzzy independent vertex sets:

$$\Psi_1 = \{x_2\}, \quad \Psi_2 = \{x_4\}, \quad \Psi_3 = \{x_1, x_3\}$$

with the degree of independence 1; $\Psi_4 = \{x_1, x_4\}$ with the degree of independence 0,8; $\Psi_5 = \{x_1, x_3, x_4\}$ with

the degree of independence 0,7; $\Psi_6 = \{x_1, x_2\}$ with the degree of independence 0,5 and $\Psi_7 = \{x_1, x_2, x_3\}$ with the degree of independence 0,4. So, its fuzzy independent set is defined as

$$\Psi_X = \{<1/1>, <1/2>, <0,7/3>, <0/4>\}.$$

Let X' be an arbitrary subset of the vertex set X . For each vertex $y \in X \setminus X'$ we define the value:

$$\gamma(y) = \max_{x \in X} \{\mu_U(y, x)\}.$$

The set X' is called a fuzzy dominating vertex set for vertex y with the degree of domination $\gamma(y)$.

The set X' is called a fuzzy dominating vertex set for the graph \tilde{G} with the degree of domination

$$\beta(X') = \min_{y \in X \setminus X'} \max_{x \in X'} \{\mu_U(y, x)\}.$$

A subset $X' \subseteq X$ of graph \tilde{G} is called a minimal fuzzy dominating **vertex** set with the degree $\beta(X')$ if the condition $\beta(X'') < \beta(X')$ is true for any subset $X'' \subset X'$.

Let a set $\tau_k = \{X_{k1}, X_{k2}, \dots, X_{kl}\}$ be given, where X_{ki} is a fuzzy dominating k -vertex set with the degree of domination β_{ki} . We define as $\beta_k^{\min} = \max\{\beta_{x_1^k}, \beta_{x_2^k}, \dots, \beta_{x_l^k}\}$. In the case $\tau_k = \emptyset$ we define $\beta_{x_k}^{\min} = \beta_{x_{k+1}}^{\min}$. Volume β_k^{\min} means that fuzzy graph \tilde{G} includes k -vertex **subgraph** with the degree of domination β_k^{\min} and doesn't include k -vertex subgraph with the degree of domination more than β_k^{\min} .

A fuzzy set $\tilde{B}_X = \{<b_1^{\min}/1>, <b_2^{\min}/2>, \dots, <b_n^{\min}/n>\}$ is called a **domination fuzzy set** of fuzzy graph \tilde{G} (Bershtein & Bozhenuk, 2001 a).

Fuzzy graph \tilde{G} (Figure 1) has five fuzzy minimal dominating vertex sets: $P_1 = \{x_1, x_2, x_3\}$ with the degree of domination 1; $P_2 = \{x_1, x_3, x_4\}$ with degree of domination 0,6; $P_3 = \{x_2, x_3\}$ with the degree of domination 0,5; $P_4 = \{x_1, x_3\}$ with degree of domination 0,2 and $P_5 = \{x_2, x_4\}$ with the degree of domination 0,3. A domination fuzzy set of fuzzy graph \tilde{G} is defined as $\tilde{B}_X = \{<0/1>, <0,5/2>, <1/3>, <1/4>\}$.

A value

$$L = \bigwedge_{i=1, k} \alpha_i = \bigwedge_{i=1, k} (1 - \bigvee_{x, y \in X_i} \mu_G(x, y))$$

is called a separation degree of fuzzy graph \tilde{G} with k colors.

The fuzzy graph \tilde{G} may be colored in a number of colors from 1 to n . In this case the separation degree L depends of the number of colors. For the fuzzy graph \tilde{G} we relate a family of fuzzy sets

$$\mathfrak{R} = \{\tilde{A}_G\}, \tilde{A}_G = \{<L_{\tilde{A}}(k) / k | k = \overline{1, n}\}$$

where $L_{\tilde{A}}(k)$ defines a degree of separation of fuzzy graph \tilde{G} with k colors.

A fuzzy set $\tilde{\gamma} = \{<L_{\tilde{\gamma}}(k) / k | k = \overline{1, n}\}$ is called a **fuzzy chromatic set** of graph \tilde{G} if the condition $\tilde{A}_G \subseteq \tilde{\gamma}$ is performed for any set $\tilde{A}_G \in \mathfrak{R}$, or else: $(\forall \tilde{A}_G \in \mathfrak{R})(\forall k = \overline{1, n})[L_{\tilde{A}}(k) \leq L_{\tilde{\gamma}}(k)]$ (Bershtein & Bozhenuk, 2001 b).

Otherwise, the fuzzy chromatic set defines a maximal separation degree of fuzzy graph \tilde{G} with $k = 1, 2, \dots, n$ colors.

For fuzzy graph \tilde{G} (Figure 1) the fuzzy chromatic set is $\tilde{\gamma}(\tilde{G}) = \{<0/1>, <0,5/2>, <1/3>\}$.

So, the fuzzy graph \tilde{G} may be colored

- by one color with the degree of separation 0. In other words, there is at least pair of vertices x_i and x_j for which the membership function $\mu_U(x_i, x_j) = 1$. In our graph, these vertices are x_4 and x_2 ;
- by 2 colors with the degree of separation 0,5 (vertices x_1, x_2 - first color, vertices x_3, x_4 - second color). In other words, between vertices of the same color there aren't edges with the membership function more than 0,5;
- by 3 colors with the degree of separation 1 (vertices x_1, x_3 - first color, vertices x_2 - second color, vertex x_4 - third color). In other words, between vertices of the same color there aren't any edges.

Fuzzy Hypergraph

Let a fuzzy hypergraph $\tilde{H} = (X, \tilde{E})$ be given, where $X = \{x_i\}$, $i \in I = \{1, 2, \dots, n\}$ - is a finite set and $\tilde{E} = \{\tilde{e}_k\}$, $\tilde{e}_k = \{<\mu_{e_k}(x) / x>\}$, $k \in K = \{1, 2, \dots, m\}$ is a family of fuzzy subsets in X (Monderson & Nair, 2000, Bershtein & Bozhenuk, 2005). Thus elements of set X are the vertices of hypergraph, a family \tilde{E} is the family of hypergraph fuzzy edges. The value $\mu_{e_k}(x) \in [0, 1]$ is an incidence degree of a vertex x to an edge \tilde{e}_k .

It is possible to see that a fuzzy hypergraph is turned in the fuzzy graph when $1 \leq \tilde{e}_k \leq 2, k \in K$.

Vertices x and y are called fuzzy adjacent vertices if there are some edge, which includes both vertices. In this case a value

$$\mu(x,y) = \bigvee_{e_k \ni \tilde{e}} \mu_{e_k}(x) \& \mu_{e_k}(y)$$

is called an adjacent degree of two vertices x and y of fuzzy hypergraph \tilde{H} .

Two edges \tilde{e}_i and \tilde{e}_j are called fuzzy adjacent edges if $\tilde{e}_i \cap \tilde{e}_j \neq \emptyset$. In this case a value

$$\mu(\tilde{e}_i, \tilde{e}_j) = \bigvee_{x \in (\tilde{e}_i \cap \tilde{e}_j)} \mu_{\tilde{e}_i \cap \tilde{e}_j}(x)$$

is called adjacent degree of edges \tilde{e}_i and \tilde{e}_j .

A fuzzy hypergraph $\tilde{H} = (X, \tilde{E})$ is convenient for representing as **fuzzy incidence matrix** $\|r_j\|_{n \times m}$, where $r_j = m_{\tilde{e}_j}(x_i)$. So, any matrix, which elements are included in the interval $[0,1]$, may be consider as fuzzy incidence matrix of some fuzzy hypergraph.

A fuzzy simple **path** $\tilde{C}(x_1, x_{q+1})$ with the length q is defined as the sequence

$$\tilde{C}(x_1, x_{q+1}) = (x_1, \mu_{\tilde{e}_1}(x_1), \tilde{e}_1, \mu_{\tilde{e}_1}(x_2), x_2, \mu_{\tilde{e}_2}(x_2), \tilde{e}_2, \dots, \tilde{e}_q, \mu_{\tilde{e}_q}(x_{q+1}), x_{q+1}),$$

where all vertices $x_1, \dots, x_q \in X$ and all edges $\tilde{e}_1, \dots, \tilde{e}_q \in \tilde{E}$ are different.

A strength of fuzzy simple path is the weakest of adjacent degrees, which are included in this path $\tilde{C}(x_1, x_{q+1})$. If two vertices x_i and x_{q+1} are connected by paths $\tilde{C}_1, \tilde{C}_2, \dots, \tilde{C}_t$ with strengths $\mu_1, \mu_2, \dots, \mu_t$, then say that vertices x_i and x_{q+1} are fuzzy connected by the strength $\mu(x_i, x_{q+1}) = \mu_1 \& \mu_2 \dots \& \mu_t$.

An internal stability degree of vertices subset X' of fuzzy hypergraph \tilde{H} is determined as:

$$\alpha_{X'} = 1 - \max_{x,y \in X'} \mu(x,y).$$

Subset $X' \subseteq X$ is called a maximal fuzzy internally stable set with the degree of internal stability $\alpha_{X'}$, if the statement $(\forall X' \supseteq X')(\alpha_{X'} < \alpha_{X'})$ is true.

Let's paint each vertex $x \in X$ of hypergraph \tilde{H} in one of k colours ($1 \leq k \leq n$) and we shall consider a X_k subset of vertices, colored identically.

The value

$$L_i = \&_{i=1,k} \alpha_i = \&_{i=1,k} (1 - \bigvee_{x,y \in X_i} \mu(x,y))$$

is called a separation degree of fuzzy hypergraph \tilde{H} at its k -colorings (Bershtein, Bozhenuk & Rozenberg, 2005)..

Fuzzy hypergraph \tilde{H} can be colored in any number of k colours and thus separation degree L depends on their number. Fuzzy hypergraph \tilde{H} we shall put in conformity family of fuzzy sets

$$\mathfrak{R} = \{\tilde{A}_{\tilde{H}}\}, \tilde{A}_{\tilde{H}} = \{< L(k) / k \mid k = \overline{1, n}\},$$

where $L(k)$ determines a separation degree of fuzzy hypergraph \tilde{H} at its certain k -colouring.

Fuzzy set $\tilde{\gamma} = \{< L_{\tilde{\gamma}}(k) / k \mid k = \overline{1, n}\}$ is called **fuzzy chromatic set** of hypergraph \tilde{H} , if for any other set $\tilde{A}_{\tilde{H}} \in \mathfrak{R}$, it is true $\tilde{A}_{\tilde{H}} \subseteq \tilde{\gamma}$. In other words, $(\forall \tilde{A}_{\tilde{H}} \in \mathfrak{R} \forall k = \overline{1, n}) [L(k) \leq L(k)]$. Or, otherwise, fuzzy chromatic set of hypergraph \tilde{H} determines the greatest separation degrees at colouring its tops in one of $1, 2, \dots, n$ colours.

Let \tilde{H} be a fuzzy hypergraph which the incidence matrix is given by:

$$I = \begin{matrix} & \tilde{e}_1 & \tilde{e}_2 & \tilde{e}_3 & \tilde{e}_4 & \tilde{e}_5 \\ \begin{matrix} x_1 \\ x_2 \\ x_3 \\ x_4 \\ x_5 \\ x_6 \end{matrix} & \begin{vmatrix} 0,8 & 0,5 & 0 & 0 & 0 \\ 1 & 0 & 0 & 0 & 0 \\ 0,4 & 1 & 0,3 & 0,7 & 0 \\ 0 & 0,6 & 0,4 & 0,2 & 1 \\ 0 & 0 & 0,7 & 1 & 0 \\ 0 & 0 & 0 & 0 & 0,4 \end{vmatrix} \end{matrix}$$

The fuzzy chromatic set for the fuzzy hypergraph is

$$\tilde{\gamma}_I = \{< 0,2 / 1 >, < 0,5 / 2 >, < 1 / 3 >\}.$$

Otherwise, the fuzzy hypergraph may be colored by one color with the degree of separation 0,2; by 2 colors with the degree of separation 0,5 (vertices x_2, x_3 and x_6 - first color, vertices x_1, x_4 и x_5 - second color); by 3 colors with the degree of separation 1 (vertices x_2 , and x_4 - first color, vertices x_1, x_5 and x_6 - second color, vertex x_3 - third color).

FUTURE TRENDS

In according to a principle of generalization L. Zadeh, the theory of fuzzy graphs and fuzzy hypergraphs will develop in a development course of nonfuzzy graphs, hypergraphs, and fuzzy sets theory.

CONCLUSION

When we consider fuzzy graphs and fuzzy hypergraphs, there is an opportunity to relate any set vertices and edges to family of partial graphs and hypergraphs with given property. For example, a sequence of edges – to family of graph paths; a sequence of vertices and edges – to family of bipartite graphs, and so on. It enables to define new properties of fuzzy graphs and hypergraphs, and to use theirs to analysis and synthesis fuzzy systems.

KEY TERMS

Binary Relation: A binary relation R from a set A to a set B is a subset of $A \times B$.

Binary Symmetric Relation: A relation R on a set A is symmetric if for all $x, y \in A$ $xRy \Rightarrow yRx$.

Fuzzy Set: A generalization of the definition of the classical set. A fuzzy set is characterized by a membership function, which maps the member of the universe into the unit interval, thus assigning to elements of the universe degrees of belongingness with respect to a set.

Graph: A graph $G = (V, E)$ is a mathematical structure consisting of two finite sets V and E . The elements of V are called vertices (or nodes), and the elements of E are called edges. Each edge has a set of one or two vertices associated to it, which are called its endpoints.

Graph Invariant: A property of a graph that is preserved by isomorphisms.

Isomorphic Graphs: Two graphs that have a structure-preserving vertex bijection between them.

Hypergraph: A hypergraph on a finite set $X = \{x_1, x_2, \dots, x_n\}$ is a family $H = \{E_1, E_2, \dots, E_m\}$ of subsets of X such that $E_i \neq \emptyset$ and

$$\bigcup_{i=1}^m E_i = X.$$

Membership Function: The membership function of a fuzzy set is a generalization of the characteristic function of crisp sets.

Multirarity Relation: A multirarity relation R between elements of sets A, B, \dots, C is a subset of $A \times B \times \dots \times C$.

Fuzzy Logic Applied to Biomedical Image Analysis

Alfonso Castro

Bernardino Arcay

University of A Coruña, Spain

INTRODUCTION

Ever since Zadeh established the basis of fuzzy logic in his famous article Fuzzy Sets (Zadeh, 1965), an increasing number of research areas have used his technique to solve and model problems and apply it, mainly, to control systems. This proliferation is largely due to the good results in classifying the ambiguous information that is typical of complex systems. Success in this field has been so overwhelming that it can be found in many industrial developments of the last decade: control of the Sendai train (Yasunobu & Miyamoto, 1985), control of air-conditioning systems, washing machines, auto-focus in cameras, industrial robots, etc. (Shaw, 1998)

Fuzzy logic has also been applied to computerized image analysis (Bezdek & Keller & Krishnapuram & Pal, 1999) because of its particular virtues: high noise insensitivity and the ability to easily handle multidimensional information (Sutton & Bezdek & Cahoon, 1999), features that are present in most digital images analyses. In fuzzy logic, the techniques that have been most often applied to image analysis have been fuzzy clustering algorithms, ever since Bezdek proposed them in the seventies (Bezdek, 1973). This technique has evolved continuously towards correcting the problems of the initial algorithms and obtaining a better classification: techniques for a better initialization of these algorithms, and algorithms that would allow the evaluation of the solution by means of validity functions. Also, the classification mechanism was improved by modifying the membership function of the algorithm, allowing it to present an adaptative behaviour; recently, kernel functions were applied to the calculation of memberships. (Zhong & Wei & Jian, 2003)

At the present moment, applications of fuzzy logic are found in nearly all Computer Sciences fields, it constitutes one of the most promising branches of Artificial

Intelligence both from a theoretic and commercial point of view. A proof of this evolution is the development of intelligent systems based on fuzzy logic.

This article presents several fuzzy clustering algorithms applied to medical images analysis. We also include the results of a study that uses biomedical images to illustrate the mentioned concepts and techniques.

BACKGROUND

Fuzzy logic is an extension of the traditional binary logic that allows us to achieve multi-evaluated logic by describing domains in a much more detailed manner and by classifying better through searches in a more extensive area. Fuzzy logic makes it possible to model the real world more efficiently: for example, whereas binary logic merely allows us to state that a coffee is hot or cold, fuzzy logic allows us to distinguish between all the possible temperature fluctuations: very hot, lukewarm, cold, very cold, etc.

Techniques based on fuzzy logic have proven to be very useful for dealing with the ambiguity and vagueness that are normally associated to digital images analysis. At what grey level do we fixate the thresholding? Where do we locate the edge in blurred objects? When is a grey level high, low, or average?

The fuzzy processing of digital images can be considered a totally different focus with respect to the traditional computerized vision techniques. It was not developed to solve a specific problem, but describes a new class of image processing techniques and a new methodology to develop them: fuzzy edge detectors, fuzzy geometric operators, fuzzy morphological operators, etc.

These features make fuzzy logic especially useful for the development of algorithms that improve medical images analysis, because it provides a framework

for the representation of knowledge that can be used in any phase of the analysis. (Wu & Agam & Roy & Armato, 2004) (Vermandel & Betrouni & Taschner & Vasseu & Rosseau, 2007)

FUZZY CLUSTERING ALGORITHMS APPLIED TO BIOMEDICAL IMAGE ANALYSIS

Medical imaging systems use a series of sensors that detect the features of the tissues and the structure of the organs, which allows us, depending on the used technique, to obtain a great amount of information and images of the area from different angles. These virtues have converted them into one of the most popular support techniques in diagnosis, and have given rise to the current distribution and variety in medical images modalities (X-Rays, PET ...) and to new modalities that are being developed (fMRI).

The complexity of the segmentation of biomedical images is entirely due to its characteristics: the large amount of data that need to be analyzed, the loss of information associated to the transition from a 3D body to a 2D representation, the great variability and complexity of the shapes that must be analyzed ... Among the most frequently applied focuses to segment medical images is the use of pattern recognition techniques, since normally the purpose of analyzing a medical digital image is the detection of a particular element or object: tumors, organs, etc.

Of all these techniques, fuzzy clustering techniques have proven to be among the most powerful ones, because they allow us to use several features of the dataset, each with their own dimensionality, and to partition these data; also, they work automatically and usually have low computational requirements. Therefore, if the problem of segmentation is defined as the partition of the image into regions that have a common feature, fuzzy clustering algorithms carry out this partition with a set of exemplary elements, called centroids, and obtain a matrix of the size of the original image and with a dimensionality equal to the number of clusters into which the image was divided; this indicates the membership of each pixel to each cluster and serves as a basis for the detection of each element.

In the next section we present a series of fuzzy clustering algorithms that can be considered to reflect the evolution in this field and its various viewpoints.

Finally, these algorithms will be used in a study that shows the use and possibilities of fuzzy logic in the analysis of biomedical images.

Fuzzy C-Means (FCM)

The FCM algorithm was developed by Bezdek (Bezdek, 1973) and is the first fuzzy clustering algorithm; it initially needs the number of clusters in which the image will be divided and a sample of each cluster. The steps of this algorithm are the following:

1. Calculation of the membership of each element to each cluster:

$$u_k(i, j) = \left(\frac{\|y(i, j) - v_k\|^{\frac{2}{m-1}}}{\sum \|y(i, j) - v_j\|^{\frac{2}{m-1}}} \right)^{-1} \quad (1)$$

2. Calculation of the new centroids of the image:

$$v_k = \frac{\sum_{i,j} u_k(i, j)^m y(i, j)}{\sum_{i,j} u_k(i, j)^m}, k = 1, \dots, C \quad (2)$$

3. If the error stays below a determined threshold, stop. In the contrary case, return to step 1.

The parameters that were varied in the analysis of the algorithm were the provided samples and the value of m .

Fuzzy K-Nearest Neighbour (FKNN)

The Fuzzy K-Nearest Neighbour (Givens Jr. & Gray & Keller, 1992) is, as its name indicates, a fuzzy variant of a hard segmentation algorithm. It needs to know the number of classes into which the set that must be classified will be divided.

The element that must be classified is associated to the class of the nearest sample among the K most similar ones. These K most similar samples are known as "neighbours"; if, for instance, the neighbours are classified from more to less similar, the destination class of the studied element will be the class of the neighbour that is first on the list.

We use the expression in Equation 3 to calculate the membership factors of the pixel to the considered clusters:

$$u_i(x) = \frac{\sum_{j=1}^K u_{ij} \left(\frac{1}{\|x - x_j\|^{\frac{2}{m-1}}} \right)}{\sum_{j=1}^K \left(\frac{1}{\|x - x_j\|^{\frac{2}{m-1}}} \right)} \quad (3)$$

where u_{ij} represents the membership factor of the j -th sample to the i -th class; x_j represents one of the K samples that are most similar to the treated pixel; x represents the pixel itself; m is a weight factor of the distance between the pixel and the samples and $u_i(x)$ represents the level of membership of the pixel x to class i .

During the analysis of this algorithm, the parameters that varied were the samples provided as initial centroids and the considered number of neighbours.

Modified Fuzzy C-Means

This algorithm is based on the work of Young Won Lim and Sang Uk Lee (Lee & Lim, 1990), who describe an algorithm for the segmentation of color images through the study of the histograms of each color band. This algorithm also relies on the classification algorithm fuzzy c-means.

The MFCM consists of two parts:

1. A hard part that studies the histograms of an image in order to obtain the number of classes, and carries out a first global classification of the image; and
2. A fuzzy part that classifies the pixels that have more difficulties in determining the class to which they belong. The pixels of this area are called "fuzzy zone".

Once obtained the initial clusters with its centroids, the algorithm uses the FCM membership function (Eq. 2) to classify the pixels. The fuzzy points are pixels between the initial clusters and pixels of clusters too little for its consideration.

Since we do not dispose of labeled simples of each class, we use the gravity centers of the clusters to calculate the membership factors of a pixel.

During the analysis of this algorithm, we varied the value of the sigma used to smoothen the histogram, the area that the initial clusters need to survive, and the security areas around the clusters.

Kernelized Fuzzy C-Means (KFCM)

This algorithm was proposed by Wu Zhong-Dong et al (Zhong & Wei & Jian, 2003) and is based on FCM, integrated with a kernel function that allows the transfer of the data to a space with more dimensionality, which makes it easier to separate the clusters.

The most often used kernel functions are the polynomial functions (Eq. 4) and the radial base functions (Eq. 5).

$$K(X, Y) = \phi(X) \cdot \phi(Y) = (X \cdot Y + b)^d \quad (4)$$

$$K(X, Y) = \phi(X) \cdot \phi(Y) = \exp\left(-\frac{(X - Y)^2}{2\sigma^2}\right) \quad (5)$$

The algorithm consists of the following steps:

1. Calculation of the membership function:

$$u_{jk} = \frac{(1/d^2(X_j, V_k))^{1/(q-1)}}{\sum_{j=1}^C (1/d^2(X_j, V_k))^{1/(q-1)}} \quad (6)$$

where

$$d^2(X_j, V_k) = K(X_j, X_j) - 2K(X_j, V_k) + K(V_k, V_k)$$

2. Calculation of the new kernel matrix $K(X_j, \hat{V}_k)$ and $K(\hat{V}_k, \hat{V}_k)$:

$$K(X_j, \hat{V}_k) = \phi(X_j) \cdot \phi(\hat{V}_k) = \frac{\sum_{i=1}^N (u_{ik})^q K(X_i, X_j)}{\sum_{i=1}^N (u_{ik})^q} \quad (7)$$

where

$$\phi(\hat{V}_k) = \frac{\sum_{j=1}^N (u_{jk}) \phi(X_j)}{\sum_{j=1}^N (u_{jk})}$$

3. Update the memberships u_{jk} to \hat{u}_{jk} by means of Equation 6.
4. If the error stays below a determined threshold, stop. In the contrary case, return to step 1.

The different parameters for the analysis of this algorithm were the initial samples.

Images Used in the Study

For the selection of the images that were used in the study (Gonzalez & Woods, 1996), we applied the traditional image processing techniques and used the histogram as basic tool. See Figure 1.

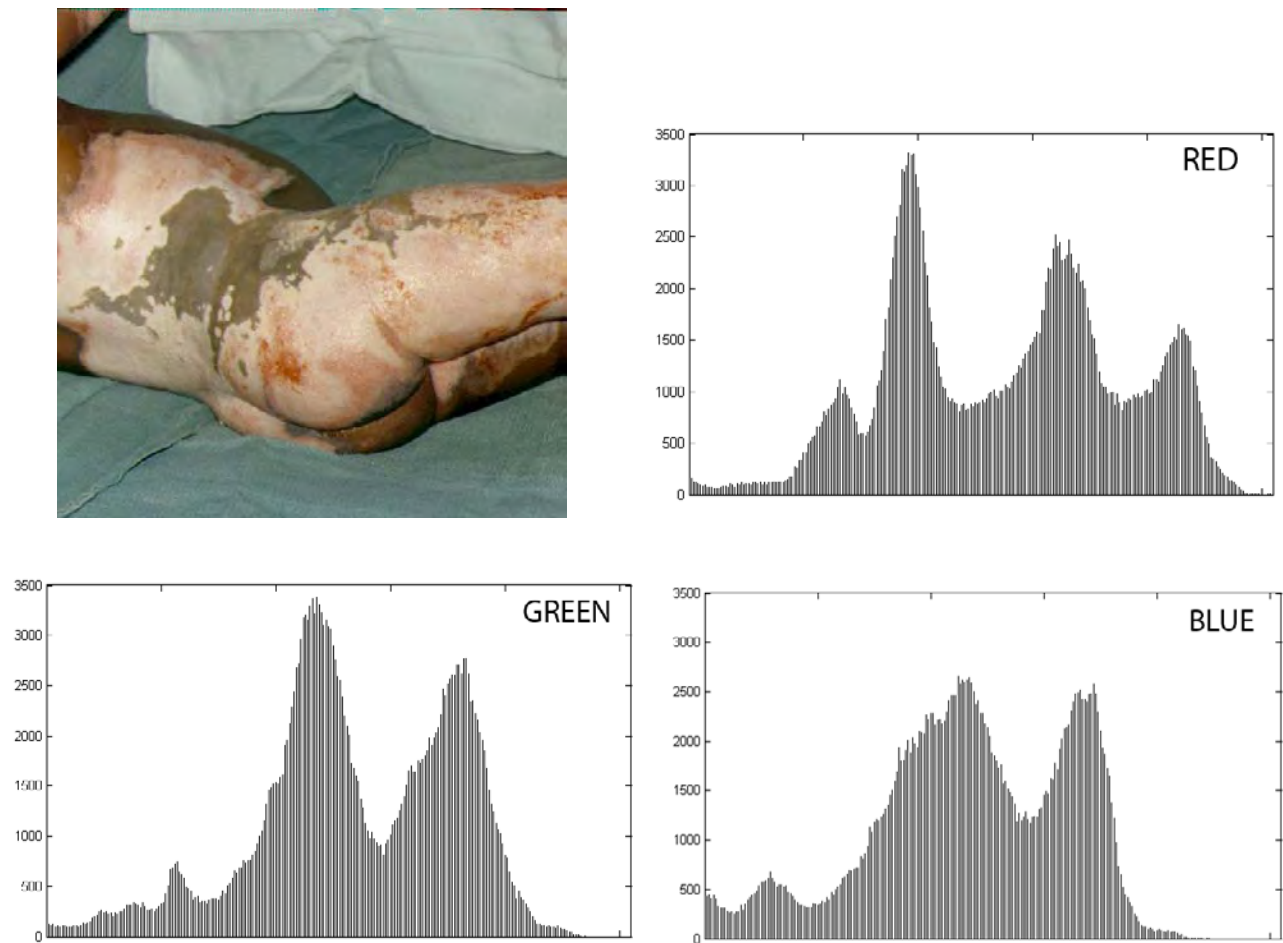

We observed that the pictures presented a high level of variation, because it was not possible to standardize the different elements that have a determining effect on them: position of the patient, luminosity, etc. We selected the pictures on the basis of a characteristic trait (bad lighting, presence of strange objects, etc.) or on their “normality” (correct lighting, good contrast, etc.). The

images were digitalized to a size of 500x500 pixels and 24 color bits per pixel, using an average scanner.

The histograms of Figure 1 show some of the characteristics that were present in most photographs. The bands with a larger amount of pixels are those of the colors red and green, because of the color of the skin and the fact that green is normally used in sanitary tissue.

The histogram is continuous and presents values in most levels, which leads us to suppose that the value of most points is determined by the combination of the three bands instead of only one band, as was to be expected. This complicates the analysis of the image with algorithms.

Figure 1. Photograph that was used in the study, and histogram for each color band

Results

The test images were divided into 3 clusters: background, healthy tissue, and burned tissue. These areas are clearly distinguished by the specialist, which allows us to build better masks to evaluate the success rate in pixel detection applied to burn wounds.

The success rate of the fuzzy clustering algorithms was first measured with Zhang's RUMA (Relative Ultimate Measurement Accuracy) (Zhang, 1996). The purpose of RUMA is to measure the quality of the segmentation in terms of the similarity of the measures

carried out on the segmented image and on the real image (Eq. 8).

$$RUMA = \frac{|R_f - S_f|}{R_f} \times 100\% \quad (8)$$

In our study, we measured the success rate by comparing the number of pixels of the burned area in the result image that coincided with pixels of the burned area in the mask.

Figure 2. Best results for the RUMA and global measurements for the: FKNN algorithm (a) and MFCM algorithm (b)

We also opted for applying a second success rate measurement, because although RUMA provides a value for the area of interest, it may not detect certain classification errors that can affect the resulting image. We use a measure that was developed by our research team and measures the clustering algorithm's performance in classifying all the pixels of the image (Eq. 9). During the development of the measure, we supposed that the error would be smaller if the error of each cluster classification were smaller, so we measured the error in the pixel classification of each cluster and weighed it against the number of pixels of that cluster.

$$error = \sum_{j=1}^n \sum_{i=1}^n \frac{F_{ij}}{MASC_j}, i \neq j \quad (9)$$

F_{ij} is the number of clusters that belong to cluster j and were assigned to cluster i , $MASC_j$ is the total amount of pixels that belong to class j , and n is the amount of clusters into which the image was divided. The value of this measurement lies between 0 and n ; in order to simplify its interpretation, it was normalized between 0 and 1.

The graphics are simplified by inverting the discrepancy values: the higher the value, the better the result.

Figure 2(a) shows the best results for the FKNN algorithm, varying the number of samples and neighbours from 1 sample per cluster to 8 samples, for both measurements.

Figure 2(b) shows the results for the MFCM algorithm, varying the threshold that was required for each area in the histogram and the sigma, for both measurements.

The FCM and FKCM algorithms are not detailed because the parameters that were varied were the value of the provided samples and the stop threshold, with a rather stable result for both measurements. In the Figure 3 we can see one of the results obtained for the algorithm FCM and the imaged labeled Q1.

Figure 4(a) shows the results for the various images of the test set for RUMA applied to all the algorithms, Figure 4(b) shows the results using global measurement.

The tests reveal great variation in the values provided for the different algorithms by each measurement; this is due to the lack of homogeneous conditions in the acquisition of the images and the ensuing differences in photographic quality.

We can also observe that the results obtained with FKCM are considerably better than the results with FCM, because the first uses a better function to calculate the pixel membership. Nevertheless, for most

Figure 3. Image labeled Q1 (left) and one of the results obtained for the FCM algorithm (right)

Figure 4. Best results for the burned area using: RUMA measurement (a) and global success rate measurement (b)

pictures the good results with FKCM are surpassed by the FKNN and MFCM algorithms. In the case of FKNN, this is due to its capacity to use several samples for each cluster, which allows a more exact calculation of the memberships and less error probability. MFCM, on the other hand, carries out a previous analysis of the

histogram, which enables it in most cases to find good centroids and make good classifications.

Even though the FKNN algorithm obtains better results, in most cases it requires a high number of samples (more than 4), which may disturb the medical expert and complicate the implantation in real clini-

cal environments. This problem does not apply to the MFCM algorithm, which calculates the samples itself; however, its success values greatly vary, and for many images we had to finetune the parameters in order to obtain good results.

FUTURE TRENDS

The field of fuzzy logic is a field that evolves continuously and is increasingly applied to industrial products.

The medical images analysis field is among the most active in computerized vision and represents an important challenge to researchers in search of new technological developments.

Fuzzy clustering algorithms constitute one of the most useful and interesting branches of fuzzy logic. Their use is expected to increase and new algorithms will appear that will provide ever better results. These algorithms will more and more often be applied to the field of medical images, where they allow us to handle new multidimensional modalities and improvements.

CONCLUSION

This article presents the results obtained by various fuzzy clustering algorithms in analyzing a set of burn wound pictures. The studied techniques obtain a high level of detection in the burned area and as such show their capacity to analyse this type of medical images. Testing however reveals a high degree of variation in the values provided by each algorithm, due to the absence of homogeneous conditions during the image acquisition and the ensuing differences in the quality of the pictures.

This study shows how the FKCM algorithm provides the best results with the smallest amount of parameters. However, if we could control the context in which the photographs are taken, the best algorithm would be MFCM, which provides better results and operates automatically.

Also, we revise the state of the art in the field of fuzzy logic and clustering algorithms, in order to show the characteristics of these techniques and their possibilities.

KEY TERMS

Fuzzification: The process of decomposing a system input and/or output into one or more fuzzy sets. Many types of curves can be used, but triangular or trapezoidal shaped membership functions are the most common.

Fuzzy Algorithm: An ordered sequence of instructions which may contain fuzzy assignments, conditional statements, repetitive statements, and traditional operations.

Fuzzy Inference Systems: A sequence of fuzzy conditional statements which may contain fuzzy assignment and conditional statements. The execution of such instructions is governed by the compositional rule of inference and the rule of preponderant alternative.

Fuzzy Operator: Operations that enable us to combine fuzzy sets. A fuzzy operator combines two fuzzy sets to give a new fuzzy set. The most frequently used fuzzy operators are the following: equality, containment, complement, intersection and union.

Medical Image: A medical specialty that uses x-rays, gamma rays, high-frequency sound waves, and magnetic fields to produce images of organs and other internal structures of the body. In diagnostic radiology the purpose is to detect and diagnose disease, whereas in interventional radiology, imaging procedures are combined with other techniques to treat certain diseases and abnormalities.

Membership Function: Gives the grade, or degree, of membership within the fuzzy set, of any element of the universe of discourse. The membership function maps the elements of the universe onto numerical values in the interval $[0, 1]$.

Segmentation: A process that partitions a digital image into disjoint (non-overlapping) regions, using a set of features or characteristics. The output of the segmentation step is usually a set of classified elements, such as tissue regions or tissue edges.

INTRODUCTION

The acquisition system is one of the most sensitive stages in a Direct Sequence Spread Spectrum (DS-SS) receiver (Peterson, Ziemer & Borth, 1995), due to its critical position in order to demodulate the received information. There are several schemes to deal with this problem, such as serial search and parallel algorithms (Proakis, 1995). Serial search algorithms have slow convergence time but their computational load is very low; on the other hand, parallel systems converge very quickly but their computational load is very high. In our system, the acquisition scheme used is the multiresolutive structure presented in (Moran, Socoró, Jové, Pijoan & Tarrés, 2001), which combines quick convergence and low computational load.

The decisional system that evaluates the acquisition stage is a key process in the overall system performance, being a drawback of the structure. This becomes more important when dealing with time-varying channels, where signal to noise ratio (called SNR) is not a constant parameter. Several factors contribute to the performance of the acquisition system (Glisic & Vucetic, 1997): channel distortion and variations, noise and interference, uncertainty about the code phase, and data randomness. The existence of all these variables led us to think about the possibility of using fuzzy logic to solve this complex acquisition estimation (Zadeh, 1973). A fuzzy logic acquisition estimator had already been tested and used in our research group to control a serial search algorithm (Alsina, Morán & Socoró, 2005) with encouraging results, and afterwards in the multiresolutive scheme (Alsina, Mateo & Socoró, 2007), and other applications to this field can be found in bibliography as (Bas, Pérez & Lagunas, 2001) or (Jang,

Ha, Seo, Lee & Lee, 1998). Several previous works have been focused in the development of acquisition systems for non frequency selective channels with fast SNR variations (Moran, Socoró, Jové, Pijoan & Tarrés, 2001) (Mateo & Alsina, 2004).

BACKGROUND

In 1964, Dr. Lofti Zadeh came out with the term *fuzzy logic* (Zadeh, 1965). The reason was that traditional logic could not answer to some questions with a simple *yes* or *no*. So, it handles the concept of partial truth. Fuzzy logic is one of the possibilities to imitate the working of a human brain, and so to try to turn artificial intelligence into real intelligence. Zadeh devised the technique as a method to solve problems for soft sciences, in particular those that involve human interaction.

Fuzzy logic has been proved to be a good option for control in very complex processes, when it is not possible to produce a mathematical model. Also fuzzy logic is recommendable for highly non-linear processes, and overall, when expert knowledge is desirable to be performed. But it is not a good idea to apply if traditional control or estimators give out satisfying results, or for problems that can be modelled in a mathematical way.

The most recent works in control and estimation using fuzzy logic applied to direct sequence spread spectrum communication systems are classified into three types. The first group uses fuzzy logic to improve the detection stage of the DS-CDMA¹ receiver, and they are presented by Bas et al and Jang et al (Bas, Pérez, & Lagunas, 2001)(Jang, Ha, Seo, Lee, & Lee, 1998). The second group uses fuzzy logic to improve interference

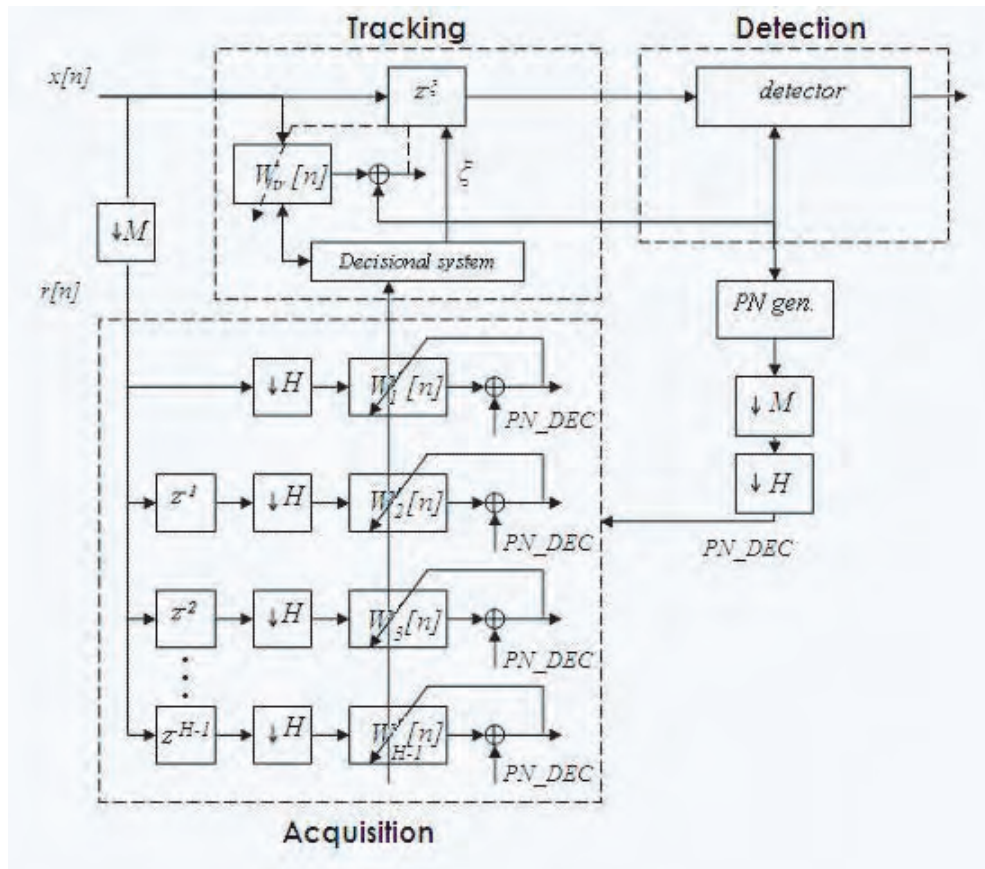

rejection, with works presented by Bas et al and by Chia-Chang et al (Bas, & Neira, 2003) (Chia-Chang, Hsuan-Yu, Yu-Fan, & Jyh-Horng, 2005). Finally, fuzzy logic techniques are also improving estimation and control in the acquisition stage of the DS-CDMA receiver, in works by Alsina et al (Alsina, Moran, & Socoró, 2005) (Alsina, Mateo, & Socoró, 2007).

ACQUISITION ESTIMATION IN DS-CDMA ENVIRONMENTS

One of the most important problems to be solved in direct sequence spread spectrum systems is to achieve a robust and precise acquisition of the pseudonoise

sequence; this is to obtain an accurate estimation of its exact phase or timing position (Proakis, 1995). In time-varying environments this fact becomes even more important because acquisition and tracking performance can heavily degrade communication demodulation reliability. In this work a new multiresolutive acquisition system with a fuzzy logic estimator is proposed (Alsina, Mateo, & Socoró, 2007). The fuzzy logic estimation improves the accuracy of the acquisition stage compared to the results for the stability controller, through the estimation of the probability of being acquired, and the signal to noise ratio in the channel, improving the results obtained for the first fuzzy logic estimator for the multiresolutive structure in (Alsina, Mateo & Socoró, 2007).

Figure 1. Multiresolutive adaptive structure for acquisition and tracking

Multiresolutive Acquisition Structure

The aim of the multiresolutive scheme presented in (Moran, Socoró, Jové, Pijoan & Tarrés, 2001) is to find the correct acquisition point in a reasonable convergence time. It gives a good trade-off between speed of convergence of the parallel systems and the low computational load of the serial search algorithms. An M order decimation is firstly applied to the input signal $x[n]^2$ as acquisition stage can accept uncertainties under the chip period, and thus to decrease the computational load of the acquisition stage. Once the signal $x[n]$ is decimated, the resulting signal $r[n]$ is fed into the filters of a multiresolutive structure (see the structure in figure 1). Note that there are H different branches that work with decimated versions of the input signal, separated in H disjoint subspaces. Each branch has an adaptive FIR LMS filter of length

$$N = \left\lceil \frac{PG}{H} \right\rceil_3,$$

trained with a decimated version of the PN sequence (PN-DEC).

Under ideal conditions, in a non-frequency selective channel with white Gaussian noise, just one of the filters should locally converge an impulse like $\lambda b_i[k]\delta[n - \tau]$, where $b[k]$ is the information bit, τ represents the delay between the input signal PN sequence and the reference one and λ is the fading coefficient for channel distorsion. The algorithm is reseted every new data symbol, and a modulus smoothing average algorithm is applied to each of the LMS solutions ($w_i[n]$) to remove the data randomness component $b_i[k]$ dependency, obtaining nonnegative and averaged impulsional responses ($Wav_i[n]$). The decisional system uses a peak detection algorithm to find which of these filters has detected the signal ($W_{con}[n]$), and the position of the maximum (τ) in this filter will give the coarse estimation of the acquisition phase.

When the acquisition point by the decisional system is restored, tracking is solved with another adaptive LMS filter ($w_r[n]$), which expands the search window around the acquisition point, using the full time resolution input signal $x[n]$. Thus, the estimation of the acquisition point (now called ξ) is refined by the tracking and the signal can be correctly demodulated.

The Fuzzy Logic Acquisition Estimation

The fuzzy logic acquisition estimator has been designed using data of the impulsional response of all the LMS filters of the structure. Their values variations give information about the probability of being correctly acquired, and also about SNR ratio variations in the channel. In the conducted experiments, the signal space has been divided into four subspaces ($H=4$), so four LMS filters compose the acquisition stage. The length of the PN sequences is $PG=127$, so each filter has

$$N = \left\lceil \frac{PG}{H} \right\rceil = 32$$

taps to converge. This input and output variables were already defined in (Alsina, Mateo & Socoró, 2007), but the rules to be evaluated have been designed in a more precise way.

Input Variables

Four different parameters have been defined as inputs in the fuzzy estimator; three of them referred to the values of the four modulus averaged acquisition LMS filters ($Wav_i[n]$), especially the LMS filter adapted to the decimated sequence PN-DEC (called $W_{con}[n]$), and one about the tracking filter ($w_r[n]$) that refines the search:

- **Ratio₁**: it is computed as the quotient of the peak value of the LMS filter $W_{con}[n]$ divided into the mean value of this filter but the maximum, as follows:

$$Ratio_1 = \frac{W_{con}[\tau]}{\frac{1}{N} \sum_{n=1; n \neq \tau}^N W_{con}[n]}$$

- **Ratio₂**: it is evaluated as the quotient of the peak value of the LMS filter $W_{con}[\tau]$ divided into the average of the value of the same position in the other three filters $Wav_i[n]$.

$$Ratio_2 = \frac{W_{con}[\tau]}{\frac{1}{H-1} \sum_{i=1; Wav_i \neq W_{con}}^H Wav_i[\tau]}$$

- $Ratio_3$: it is obtained as the quotient of the peak value of the LMS filter $W_{con}[\tau]$ divided into the mean value of the three other filters $Wav_i[n]$.

$$Ratio_3 = \frac{W_{con}[\tau]}{\frac{1}{H-1} \sum_{i=1; Wav_i \neq W_{con}}^H \frac{1}{N} \sum_{n=1}^N Wav_i[n]}$$

- $Ratio_{1_track}$: it is computed as the quotient of the peak value of the LMS tracking filter $w_{tr}[\xi]$, being ξ the most precise estimation of the correct acquisition point, divided into the mean value of the same filter but the maximum.

$$Ratio_{1_track} = \frac{w_{tr}[\xi]}{\frac{1}{N} \sum_{n=1; n \neq \xi}^N w_{tr}[n]}$$

These parameters have been chosen due to the information they contain about the probability of being acquired, and also about the SNR level in the channel and its variations. They value variations give good estimations about acquisition quality and a good measure for SNR, with the appropriate definition of IF-THEN rules.

Output Variables

The results will be obtained using a defuzzification method based on the centroid (Leekwijck & Kerre,

Figure 2. Variable acquisition for all input variables combinations

1999). Two output variables will be computed. *Acquisition*, giving a value in the range of $[0,1]$, being zero when it is *Not Acquired* and one if it is *Acquired*. Three more fuzzy sets have been defined between the extreme values; *Probably Not Acquired*, *Not Determined* and *Probably Acquired*. *Acquisition* will show a value of reliability for the correct demodulation of the detector. The multiresolutive scheme only gives an estimation of the acquisition point, and *Acquisition* value evaluates the probability of being acquired, and so, the consistency of the bit demodulation done by the receiver.

The second variable is *SNR Estimation* which gives a value (in the range of $[-30,0]$ dBs in our experiment) of the estimated SNR value in the channel. *SNR Estimation* will give us information about channel conditions; this will help not only in acquisition and tracking, but

also in detection as in (Verdú, 1998) or (Alsina, Morán & Socoró, 2005).

If-Then Rules

A total of sixty rules have been used to define the two outputs in function of the input values, evolving the set of rules used in (Alsina, Mateo & Socoró). In figure 2 the surface for *Acquisition* for all input variables and figure 3 shows the surface for *SNR Estimation* for all inputs. Rules have been defined to take into account the best performance, in its range, of each input parameter value to design the two outputs of the fuzzy estimator. This means the value range is only considered where their estimations are more reliable for both outputs.

Figure 3. Variable SNR Estimation for all input variables combinations

The most improved estimation for the output *Acquisition* is the correspondence to *Not Determined*; this means that the input parameters have no coherent values of *Acquisition* or *Not Acquisition* by themselves. To obtain a precise output value, the fuzzy estimator evaluates the degree of implication of each input parameter to the membership functions, and projects this implication to the fuzzy sets of the output variable *Acquisition*, in order to obtain its value through defuzzification. $Ratio_1$ and $Ratio_{1track}$ are the best input parameters to estimate *Acquisition* when channel conditions are good; these two parameters are supported by $Ratio_2$ and $Ratio_3$ when SNR worsen. The precision of the critical estimations has been improved in the design of the new rules for the fuzzy estimator.

On the other hand, *SNR Estimation* most robust evaluations are made by $Ratio_2$ and $Ratio_3$; they are improved by $Ratio_{1track}$ when SNR is high, and by $Ratio_1$ when SNR is very low. As can be observed in figure 3, these variables highly correlate with *SNR Estimation* value.

Results

In this section the results obtained with the new acquisition and SNR fuzzy logic estimator will be summarized. Several simulations using an Additive White Gaussian Noise channel (AWGN), some of them with very fast SNR changes, have been done to show the performance of the fuzzy estimator in terms of reliability and stability.

Fuzzy Estimator Acquisition Reliability vs. Stability Control

A previous acquisition estimation was obtained using a *stability* control (Moran, Socoró, Jové, Pijoan & Tarrés, 2001), that took into account preservation of the acquisition point for evaluation and comparison purposes. It considered that the system was acquired only due to continuous repetitions of the acquisition point given by the multiresolutive scheme. This *stability* control gave a binary response about the performance

Figure 4. % of correct estimation of acquisition using the new fuzzy estimator against the stability Control

of the system. Despite its good performance, being observed in figure 4, the new fuzzy approach improves the results for wider SNR range. The quality of the fuzzy acquisition estimation is much better for very low SNR compared to the *stability* control, and its global performance for the whole range of SNR in our tests is improved. The *stability* control is not a good estimator for critical SNR (considered around -15dBs), and it decreases its reliability when SNR decreases. Despite showing similar performance around critical SNR, the fuzzy logic estimation of *Acquisition* improves its performance for worse SNR ratios, being over 90% of correct estimation all the simulations along.

Fuzzy SNR Estimation in Time Varying Channels

In figure 5.a the acquisition system has been simulated in an AWGN channel, forcing severe and very fast SNR changes in order to evaluate the convergence speed of the SNR estimator. *SNR Estimation* mean value, being a very variable value, is obtained through an exponential smoothing average filter, and compared to the SNR in the AWGN channel. The SNR in the channel is estimated

quite precisely until very low SNR (near -20dBs) by the fuzzy block, as the input parameters are not stable enough to make a good prediction for lower values; this is similar to what happens for *Acquisition* estimation. To observe the recovery of the fuzzy estimator in case of fast SNR changes in the channel, a detail of *SNR Estimation* is shown in figure 5.b. This information shows the channel state to the receiver, and allows further work to improve reliability of the demodulation by means of different approaches (Verdú, 1998).

FUTURE TRENDS

Future work will be focused on improving the estimation for the SNR in the fuzzy system. Another goal to be reached is to increase the stability against channel changes using previous detected symbols, obtaining a system with feedback. The fuzzy estimator outputs will be used to design a controller for the acquisition and tracking structure. Its aim will be to improve the stability of estimation of the correct acquisition point (ξ) through an effective and robust control of its variations for sudden channel changes, so memory will be added to the fuzzy logic estimator. This way the estimator is

Figure 5. a) SNR estimation in a varying SNR channel; b) Detail of SNR Estimation when adapting to an instantaneous SNR variation

converted in a controller, and the whole performance of the receiver is improved.

Further research will also take into account multipath channel conditions and possible variations, including rake-based receiver detection, in order to reach a good acquisition and tracking performance in ionospheric channels. Furthermore, the reliability of the results encourages us to use the acquisition estimation to minimize the computational load of the acquisition system for proper channel conditions, thorough decreasing the number of iterations to converge in the LMS adaptive filters. A more efficient fuzzy logic control can be designed in order to achieve a better trade-off between computational load (referred to the LMS filters adaptation) and acquisition point estimation accuracy (ξ).

CONCLUSION

The new proposed acquisition system estimator has already been exposed, and some results have been compared against a *stability* control strategy within the multiresolutive acquisition system in a variant SNR environment. The main advantage of a multiresolutive fuzzy estimator is its reliability when evaluating the probability of acquisition, also its stability, and its quick convergence when there are fast channel SNR changes. The computational load of a fuzzy estimator is higher than the same cost in a *stability* control. The mean number of FLOPS in a DSP needed to do all the process is greater compared to the conventional stability control. This has to be taken into account because the multiresolutive structure should make its computational cost minimum to work on-line with the received data. Further work will be done to compare the computational load added to the structure to the global improvements of the multiresolutive receiver, to decide whether this cost increase is affordable for the acquisition system, or it is not.

KEY TERMS

Defuzzification: After computing the fuzzy rules, and evaluating the fuzzy variables, this is the process the system follows to obtain a new membership function for each output variable.

Degree of Truth: It denotes the extent to which a proposition is true. It is important to not be confused with the concept of probability.

Fuzzy Logic: Fuzzy logic was derived from Fuzzy Set theory, working with a reason that it is approximate rather than precise, deducted from the typical predicate logic.

Fuzzy Sets: Fuzzy sets are sets whose members have a degree of membership. They were introduced to be an extension of the classical sets, whose elements' membership was assessed by binary numbers.

Fuzzification: It is the process of defining the degree of membership of a crisp value for each fuzzy set.

IF-THEN Rules: They are the typical rules used by expert fuzzy systems. The IF part is the antecedent, also named premise, and the THEN part is the conclusion.

Linguistic Variables: They take on linguistic values, which are words, with associated degrees of membership in each set.

Linguistic Term: It is a subjective category for a linguistic variable. Each linguistic term is associated with a fuzzy set.

Membership Function: It is the function that gives the subjective measures for the linguistic terms.

ENDNOTES

- ¹ DS-CDMA stands for Direct Sequence Code Division Multiple Access.
- ² The received signal $x[n]$ is sampled at M samples per chip in order to give the necessary time resolution for the tracking stage.
- ³ where PG is the length of the pseudonoise sequences, also called PN sequences and 'ceil(x)' (expressed as $N = \lceil x \rceil$) is the smaller integer greater than x .

Fuzzy Rule Interpolation

Szilveszter Kovács

University of Miskolc, Hungary

INTRODUCTION

The “fuzzy dot” (or fuzzy relation) representation of fuzzy rules in fuzzy rule based systems, in case of classical fuzzy reasoning methods (e.g. the Zadeh-Mamdani-Larsen Compositional Rule of Inference (CRI) (Zadeh, 1973) (Mamdani, 1975) (Larsen, 1980) or the Takagi - Sugeno fuzzy inference (Sugeno, 1985) (Takagi & Sugeno, 1985)), are assuming the completeness of the fuzzy rule base. If there are some rules missing i.e. the rule base is “sparse”, observations may exist which hit no rule in the rule base and therefore no conclusion can be obtained. One way of handling the “fuzzy dot” knowledge representation in case of sparse fuzzy rule bases is the application of the Fuzzy Rule Interpolation (FRI) methods, where the derivable rules are deliberately missing. Since FRI methods can provide reasonable (interpolated) conclusions even if none of the existing rules fires under the current observation. From the beginning of 1990s numerous FRI methods have been proposed. The main goal of this article is to give a brief but comprehensive introduction to the existing FRI methods.

BACKGROUND

Since the classical fuzzy reasoning methods (e.g. the Zadeh-Mamdani-Larsen CRI) are demanding complete rule bases, the classical rule base construction claims a special care of filling all the possible rules. In case if the rule base is “sparse” (some rules are missing), observations may exist which hit no rule and hence no conclusion can be obtained. In many application areas of fuzzy control structures, the accidental lack of conclusion is hard to explain, or meaningless (e.g. in steering control of a vehicle). This case one obvious solution could be to keep the last real conclusion instead of the missing one, but applying historical data automatically to fill undeliberately missing rules could cause unpredictable side effects. Another solution for the same problem is the application of the fuzzy rule

interpolation (FRI) methods, where the derivable rules are deliberately missing. The rule base of an FRI controller is not necessarily complete, since FRI methods can provide reasonable (interpolated) conclusions even if none of the existing rules fires under the current observation. It could contain the most significant fuzzy rules only, without risking the chance of having no conclusion for some of the observations. On the other hand most of the FRI methods are sharing the burden of high computational demand, e.g. the task of searching for the two closest surrounding rules to the observation, and calculating the conclusion at least in some characteristic α -cuts. Moreover in some methods the interpretability of the fuzzy conclusion gained is also not straightforward (Kóczy & Kovács, 1993). There have been a lot of efforts to rectify the interpretability of the interpolated fuzzy conclusion (Tikk & Baranyi, 2000). In (Baranyi, Kóczy & Gedeon, 2004) Baranyi *et al.* give a comprehensive overview of the recent existing FRI methods. Beyond these problems, some of the FRI methods are originally defined for one dimensional input space, and need special extension for the multidimensional case (e.g. (Jenei, 2001), (Jenei, Klement & Konzel, 2002)). In (Wong, Tikk, Gedeon & Kóczy, 2005) Wong *et al.* gave a comparative overview of the recent multidimensional input space capable FRI methods. In (Jenei, 2001) Jenei introduced a way for axiomatic treatment of the FRI methods. In (Perfilieva, 2004) Perfilieva studies the solvability of fuzzy relation equations as the solvability of interpolating and approximating fuzzy functions with respect to a given set of fuzzy rules (e.g. fuzzy data as ordered pairs of fuzzy sets). The high computational demand, mainly the search for the two closest surrounding rules to an arbitrary observation in the multidimensional antecedent space turns many of these methods hardly suitable for real-time applications. Some FRI methods, e.g. the method introduced by Jenei *et al.* in (Jenei, Klement & Konzel, 2002), eliminate the search for the two closest surrounding rules by taking all the rules into consideration, and therefore speeding up the reasoning process. On the other hand, keeping the goal of con-

structuring fuzzy conclusion, and not simply speeding up the reasoning, they still require some additional (or repeated) computational steps for the elements of the level set (or at least for some relevant α levels). An application oriented aspect of the FRI emerges in (Kovács, 2006), where for the sake of reasoning speed and direct real-time applicability, the fuzziness of fuzzy partitions replaced by the concept of Vague Environment (Klawonn, 1994).

In the followings, the brief structure of several FRI methods will be introduced in more details.

FUZZY RULE INTERPOLATION METHODS

One of the first FRI techniques was published by Kóczy and Hirota (Kóczy & Hirota, 1991). It is usually referred as KH method. It is applicable to convex and normal fuzzy (CNF) sets in single input and single output (SISO) systems. The KH method takes into consideration only the two closest surrounding (flanking) rules to the observation. It determines the conclusion by its α -cuts in such a way that the ratio of distances between the conclusion and the consequents should be identical with the ratio of distances between the observation and the antecedents for all important α -cuts. The applied formula:

$$d(A^*, A_1) : d(A^*, A_2) = d(B^*, B_1) : d(B^*, B_2),$$

can be solved for the required conclusion B^* for relevant α -cuts after decomposition. Where $A_1 \rightarrow B_1$ and $A_2 \rightarrow B_2$ are the two flanking rules of the observation A^* and $d: F(X) \times F(X) \rightarrow R$ is a distance function of fuzzy sets (in case of the KH method it was calculated as the distance of the lower and upper end points of the α -cuts) (see e.g. on Fig. 1.).

It is shown in, e.g. in (Kóczy & Kovács, 1993), (Kóczy & Kovács, 1994) that the conclusion of the KH method is not always directly interpretable as fuzzy set (see e.g. on Fig. 1.). This drawback motivated many alternative solutions. The first modification was proposed by Vass, Kalmár and Kóczy (Vass, Kalmár & Kóczy, 1992) (referred as VKK method), where the conclusion is computed based on the distance of the centre points and the widths of the α -cuts, instead of their lower and upper end point distances. The VKK method extends the applicability of the KH method, but it was still strongly depends on the membership shape of the fuzzy sets (e.g. it was unable to handle singleton antecedent sets, as the width of the antecedent's support must not be zero).

In spite of the known restrictions, the KH method is still popular because of its simplicity. Subsequently it was generalized in several ways. Among them the stabilized KH interpolator was emerged, as it was proved

Figure 1. KH method for two SISO rules: $A_1 \rightarrow B_1$ and $A_2 \rightarrow B_2$, conclusion y of the observation x

to hold the universal approximation property in (Tikk, Joó, Kóczy, Várlaki, Moser & Gedeon, 2002) and (Tikk, 2003). This method takes into account all the rules of the rule base in the calculation of the conclusion. The method adapts a modification of the *Shepard operator* based interpolation (Shepard, 1968). The rules are taken into account in extent to the inverse of the distance between their antecedents and the observation. The universal approximation property holds if the distance function is raised to the power of at least the number of the antecedent dimension.

Another modification of KH method is the modified alpha-cut based interpolation method (referred as MACI) (fully extended in (Tikk & Baranyi, 2000)), which alleviates completely the abnormality problem. MACI's main idea is the following: it transforms fuzzy sets of the input and output universes to such a space where abnormality is excluded, then computes the conclusion there, which is finally transformed back to the original space. MACI uses vector representation of fuzzy sets. The original method was introduced in (Yam & Kóczy, 1997) and it was applicable for CNF sets only. This restriction was latter relaxed in (Tikk, Baranyi, Gedeon & Muresan 2001) by paying its expanse in higher computational demand than the original method. MACI is one of the most applied FRI methods (Wong, Tikk, Gedeon & Kóczy, 2005), since it preserves advantageous computational and approximate nature of KH method, while it excludes its chance for abnormal conclusion.

Another FRI method was proposed by Kóczy *et al.* in (Kóczy, Hirota & Gedeon, 1997). It takes into consideration only the two closest surrounding rules to the observation and its main idea is the conservation of the "relative fuzziness" (referred as CRF method). This notion means that the left (and right) fuzziness of the approximated conclusion in proportion to the flanking fuzziness of the neighbouring consequent should be the same as the left (and right) fuzziness of the observation in proportion to the flanking fuzziness of the neighbouring antecedent. The original method is restricted to CNF sets only.

An improved fuzzy interpolation technique for multidimensional input spaces (referred as IMUL) was originally proposed in (Wong, Gedeon & Tikk, 2000), and described more detailed in (Wong, Tikk, Gedeon & Kóczy, 2005). IMUL applies a combination of CRF and MACI methods, and mixes the advantages of both. The core of the conclusion is determined by MACI method,

while its flanks by CRF (the method is restricted to trapezoidal membership functions). The main advantages of this method are its applicability for multi-dimensional problems and its relative simplicity.

Conceptually different approaches were proposed in (Baranyi, Kóczy & Gedeon, 2004) based on the relation, semantic and inter-relational features of the fuzzy sets. The family of these methods applies a two step "General Methodology" (referred as GM). The notation also reflects the feature, that methods based on GM can handle arbitrary shaped fuzzy sets. The basic concept is to divide the task of the FRI into two main steps. The first step is to determine the reference point of the conclusion based on the ratio of the distances between the reference points of the observation and the antecedents. Then accomplishing the first step, based on the existing rules a new, interpolated rule is generated for the reference point of the observation and the reference point of the conclusion. In the second step of the method, a single rule reasoning method (revision function) is applied to determine the final fuzzy conclusion based on the similarity of the fuzzy observation and the antecedent of the new "interpolated" rule. For both the main steps of GM numerous solutions exists, therefore the GM stands for an FRI concept, or a family of FRI methods.

A rather different application oriented aspect of the FRI emerges in the concept of the Fuzzy Interpolation based on Vague Environment FRI method (referred as FIVE), originally introduced in (Kovács, 1996), (Kovács & Kóczy, 1997a), (Kovács & Kóczy, 1997b) and extended with the ability of handling fuzzy observation in (Kovács, 2006). It was developed to fit the speed requirements of direct fuzzy control, where the conclusions of the fuzzy controller are applied directly as control actions in a real-time system. The main idea of the FIVE method is based on the fact that most of the control applications serves crisp observations and requires crisp conclusions from the controller. Adopting the idea of the vague environment (Klawonn, 1994), FIVE can handle the antecedent and consequent fuzzy partitions of the fuzzy rule base by scaling functions (Klawonn, 1994) and therefore turn the fuzzy interpolation to crisp interpolation. In FIVE any crisp interpolation, extrapolation, or regression method can be adapted very simply for FRI. Because of its simple multidimensional applicability, in FIVE, originally the *Shepard operator* based interpolation (Shepard, 1968) was adapted.

FUTURE TRENDS

Future trends of the FRI methods include the appearance of numerous hybrid FRI methods i.e. neuro-FRI, genetic-FRI for (depending on the application area) gradient based, or gradient free parameter optimisation of the FRI model. Future trends also directed to extended number of practical applications of the FRI. Recently a freely available comprehensive FRI toolbox (Johanyák, Tikk, Kovács & Wong, 2006) and an FRI oriented web site (<http://fri.gamf.hu>) were appeared for aiding and guiding the future FRI applications.

CONCLUSION

There are relatively few Fuzzy Rule Interpolation (FRI) techniques can be found among the practical fuzzy rule based applications. On one hand the FRI methods are not widely known, and some of them have limitations from practical application point of view, e.g. can be applied only in one dimensional case, or defined based on the two closest surrounding rules of the actual observation. On the other hand enabling the application of sparse rule bases the FRI methods can dramatically simplify the way of fuzzy rule base creation, since FRI methods can provide reasonable (interpolated) conclusions even if none of the existing rules fires under the current observation. Therefore these methods can save the expert from dealing with derivable rules and help to concentrate on cardinal actions only and hence simplify the rule base creation itself. Thus, compared to the classical fuzzy CRI, the number of the fuzzy rules needed to be handled during the design process, could be dramatically reduced (see e.g. in (Kovács, 2005)). Moreover in case of parameter optimisation of the sparse FRI model (hybrid FRI methods), the reduced FRI rule base size could also means reduction in the size of the optimisation search space, and hence it can lead to quicker optimisation algorithms too.

KEY TERMS

α -Cut of a Fuzzy Set: Is a crisp set, which holds the elements of a fuzzy set (on the same universe of discourse) whose membership grade is greater than, or equal to α . (In case of "strong" α -cut it must be greater than α .)

ε -Covering Fuzzy Partition: The fuzzy partition (a set of linguistic terms (fuzzy sets)) ε -covers the universe of discourse, if for all the elements in the

universe of discourse a linguistic term exists, which have a membership value greater or equal to ε .

Complete (or Dense) Fuzzy Rule Base: A fuzzy rule base is complete, or dense if all the input universes are ε -covered by rule antecedents, where $\varepsilon > 0$. In case of Complete Fuzzy Rule Base, for all the possible multidimensional observations, a rule antecedent must exist, which has a nonzero activation degree. Note, that completeness of the fuzzy rule base is not equivalent with covering fuzzy partitions on each antecedent universe (required but not sufficient in multidimensional case). Usually the number of the rules of a complete rule base is $O(M^I)$, where M is the average number of the linguistic terms in the fuzzy partitions and I is the number of the input universe.

Convex and Normal Fuzzy (CNF) Set: A fuzzy set defined on a universe of discourse holds total ordering, which has a height (maximal membership value) equal to one (i.e. normal fuzzy set), and having membership grade of any elements between two arbitrary elements greater than, or equal to the smaller membership grade of the two arbitrary boundary elements (i.e. convex fuzzy set).

Fuzzy Compositional Rule of Inference (CRI): The most common fuzzy inference method. The fuzzy conclusion is calculated as the fuzzy composition (Klir & Folger, 1988) of the fuzzy observation and the fuzzy rule base relation (see “Fuzzy dot” representation of fuzzy rules). In case of the Zadeh - Mamdani - Larsen max-min compositional rule of inference (Zadeh, 1973) (Mamdani, 1975) (Larsen, 1980) the applied fuzzy composition is the max-min composition of fuzzy relations (“max” stands for the applied s-norm and “min” for the applied t-norm fuzzy operations).

“Fuzzy Dot” Representation of Fuzzy Rules: The most common understanding of the If-Then fuzzy rules.

The fuzzy rules are represented as a fuzzy relation of the rule antecedent and the rule consequent linguistic terms. In case of the Zadeh - Mamdani - Larsen compositional rule of inference (Zadeh, 1973) (Mamdani, 1975) (Larsen, 1980) the fuzzy rule relations are calculated as the fuzzy cylindric closures (t-norm of the cylindric extensions) (Klir & Folger, 1988) of the antecedent and the rule consequent linguistic terms.

Fuzzy Rule Interpolation: A way for fuzzy inference by interpolation of the existing fuzzy rules based on various distance and similarity measures of fuzzy sets. A suitable method for handling sparse fuzzy rule bases, since FRI methods can provide reasonable (interpolated/extrapolated) conclusions even if none of the existing rules fires under the current observation.

Sparse Fuzzy Rule Base: A fuzzy rule base is sparse, if an observation may exist, which hits no rule antecedent. (The rule base is not complete.)

Vague Environment (VE): The idea of a VE is based on the similarity (or in this case the indistinguishability) of the considered elements. In VE the fuzzy membership function $\mu_A(x)$ is indicating level of similarity of x to a specific element a that is a representative or prototypical element of the fuzzy set $\mu_A(x)$, or, equivalently, as the degree to which $x \in X$ is indistinguishable from $a \in X$ (Klawonn, 1994). Therefore the α -cuts of the fuzzy set $\mu_A(x)$ are the sets which contain the elements that are $1-\alpha$ -indistinguishable from a . Two values in a VE are ε -distinguishable if their distance is greater than ε . The distances in a VE are weighted distances. The weighting factor or function is called *scaling function (factor)* (Klawonn, 1994). If the VE of a fuzzy partition (the scaling function or at least the approximate scaling function (Kovács, 1996), (Kovács & Kóczy, 1997b)) exists, the member sets of the fuzzy partition can be characterized by points in that VE.

Fuzzy Systems Modeling: An Introduction

Young Hoon Joo

Kunsan National University, Korea

Guanrong Chen

City University of Hong Kong, China

INTRODUCTION

The basic objective of system modeling is to establish an input-output representative mapping that can satisfactorily describe the system behaviors, by using the available input-output data based upon physical or empirical knowledge about the structure of the unknown system.

BACKGROUND

Conventional system modeling techniques suggest constructing a model described by a set of differential or difference equations. This approach is effective only when the underlying system is mathematically well-defined and precisely expressible. They often fail to handle uncertain, vague or ill-defined physical systems, and yet most real-world problems do not obey such precise, idealized, and subjective mathematical rules. According to the incompatibility principle (Zadeh, 1973), as the complexity of a system increases, human's ability to make precise and significant statements about its behaviors decreases, until a threshold is reached beyond which precision and significance become impossible. Under this principle, Zadeh (1973) proposed a modeling method of human thinking with fuzzy numbers rather than crisp numbers, which had eventually led to the development of various fuzzy modeling techniques later on.

MAIN FOCUS OF THE CHAPTER

Structure Identification

In structure identification of a fuzzy model, the first step is to select some appropriate input variables from the collection of possible system inputs; the second

step is to determine the number of membership functions for each input variable. This process is closely related to the partitioning of input space. Input space partitioning methods are useful for determining such structures (Wang & Mendel, 1996).

Grid Partitioning

Figure 1 (a) shows a typical grid partition in a two-dimensional input space. Fuzzy grids can be used to generate fuzzy rules based on system input-output training data. Also, a one-pass build-up procedure can avoid the time-consuming learning process, but its performance depends heavily on the definition of the grid. In general, the finer the grid is, the better the performance will be. Adaptive fuzzy grid partitioning can be used to refine and even optimize this process. In the adaptive approach, a uniformly partitioned grid may be used for initialization. As the process goes on, the parameters in the antecedent membership functions will be adjusted. Consequently, the fuzzy grid evolves. The gradient descent method may then be used to optimize the size and location of the fuzzy grid regions and the overlapping degree among them. The major drawback of this grid partition method is that the performance suffers from an exponential explosion of the number of inputs or membership functions as the input variables increase, known as the "curse of dimensionality," which is a common issue for most partitioning methods.

Tree Partitioning

Figure 1 (b) visualizes a tree partition. The tree partitioning results from a series of guillotine cuts. Each region is generated by a guillotine cut, which is made entirely across the subspace to be partitioned. At the $(k - 1)$ st iteration step, the input space is partitioned into k regions. Then a guillotine cut is applied to one of

these regions to further partition the entire space into $k + 1$ regions. There are several strategies for determining which dimension to cut, where to cut at each step, and when to stop. This flexible tree partitioning algorithm resolves the problem of curse of dimensionality. However, more membership functions are needed for each input variable, and they usually do not have clear linguistic meanings; moreover, the resulting fuzzy model consequently is less descriptive.

Scatter Partitioning

Figure 1 (c) illustrates a scatter partition. This method extracts fuzzy rules directly from numerical data (Abe & Lan, 1995). Suppose that a one-dimensional output, y , and an m -dimensional input vector, \underline{x} , are available. First, the output space is divided into n intervals, $[y_0, y_1], (y_1, y_2], \dots, (y_{n-1}, y_n]$, where the i th interval is called “output interval i .” Then, activation hyperboxes are determined, which define the input region corresponding to the output interval i , by calculating the minimum and maximum values of the input data for each output interval. If the activation hyperbox for the output interval i overlaps with the activation hyperbox for the output interval j , then the overlapped region is defined as an inhibition hyperbox. If the input data for output intervals i and/or j exist in the inhibition hyperbox, then within this inhibition hyperbox one or two additional activation hyperboxes will be defined. Moreover, if two activation hyperboxes are defined and they overlap, then an additional inhibition hyperbox

is further defined. This procedure is repeated until overlapping is resolved.

Parameters Identification

After the system structure has been determined, parameters identification is in order. In this process, the optimal parameters of a fuzzy model that can best describe the input-output behavior of the underlying system are searched by optimization techniques.

Sometimes, structure and parameters are identified under the same framework through fuzzy modeling. There are virtually many different approaches to modeling a system using the fuzzy set and fuzzy system theories (Chen & Pham, 1999, 2006), but the classical least-squares optimization and the general Genetic Algorithm (GA) optimization techniques are most popular. They are quite generic, effective, and competitive with other successful non-fuzzy types of optimization-based modeling methods such as neural networks and statistical Monte Carlo.

An Approach Using Least-Squares Optimization

A fuzzy system can be described by the following generic form:

$$f(\underline{x}) = \sum_{k=1}^m \alpha_k g_k(\underline{x}) = \underline{\alpha}^T \underline{g}(\underline{x}) \quad (1)$$

Figure 1. Three typical MISO partitioning methods

where $\underline{\alpha} = [\alpha_1, \dots, \alpha_m]^T$ are constant coefficients and

$$g_k(\underline{x}) = \frac{\prod_{i=1}^n \mu_{x_{kj}}(\underline{x})}{\sum_{k=1}^m \left(\prod_{i=1}^n \mu_{x_{kj}}(\underline{x}) \right)}, k = 1, \dots, m \quad (2)$$

are the basis functions, in which $\mu_{x_{kj}}(\cdot)$ are the chosen membership functions. Suppose that the real system output is

$$y(t) = \sum_{k=1}^m \alpha_k g_k(\underline{x}) + e(t) \quad (3)$$

where $y(t)$ is the system output and $e(t)$ represents the modeling error, which is assumed to be uncorrelated with the fuzzy basis functions $\{g_k(\cdot)\}_{k=1}^m$ in this discussion.

Suppose that n pairs of system input-output data are given: $(\underline{x}_d(t_i), y_d(t_i))$, $i = 1, \dots, n$. The goal is to find the best possible fuzzy basis functions, such that the total least-squares error between the data set and the system outputs $\{y(t_i)\}_{i=1}^n$ is minimized. To do so, the linear model (3) is first written in a matrix form over the time domain $t_1 < \dots < t_n$, namely,

$$\underline{y} = G\underline{\alpha} + \underline{e}$$

where $\underline{y} = [y(t_1), \dots, y(t_n)]^T$, $\underline{e} = [e(t_1), \dots, e(t_n)]^T$, and

$$G := [\underline{g}_1, \dots, \underline{g}_n]^T = \begin{bmatrix} g_1(t_1) & \dots & g_m(t_1) \\ \vdots & & \vdots \\ g_1(t_n) & \dots & g_m(t_n) \end{bmatrix}$$

with $\underline{g}_j = [g_j(t_1), \dots, g_j(t_n)]^T$, $j = 1, \dots, m$.

The first step is to transform the set of numbers, $g_i(t_j)$, $i = 1, \dots, m$, $j = 1, \dots, n$, into a set of orthogonal basis vectors, and only significant basis vectors are used to form the final least-squares optimization. Here, the Gaussian membership functions

$$\mu_{x_{kj}}(x_k) = c_{kj} \exp\left\{-\left(x_k - \bar{x}_{kj} / \sigma_{kj}\right)^2 / 2\right\}$$

are used as an example to illustrate the computational algorithm.

One approach to initializing the fuzzy basis functions is to choose n initial basis functions, $g_k(x)$, in the

form of (2) with $m = n$ in this discussion, and initially with $c_{kj} = 1$, $\bar{x}_{kj} = x_k(t_j)$, and

$$\sigma_{kj} = \frac{1}{m_l} \left[\max\{x_k(t_j), j = 1, \dots, n\} - \min\{x_k(t_j), j = 1, \dots, n\} \right], k = 1, \dots, n$$

where m_l is the number of the basis functions in the final expression, which is determined by the designer based on experience (usually, $m_l < n$).

After choosing the initial fuzzy basis functions, the next step is to select the most significant ones among them. This process is based on the classical Gram-Schmidt orthogonalization, while c_{kj} , \bar{x}_{kj} , and σ_{kj} are all fixed:

Step 1. For $j = 1$, compute

$$\underline{w}_1^{(i)} = g_i(\underline{x}_d) = [g_i(x_d(t_1)), \dots, g_i(x_d(t_n))]^T$$

$$h_1^{(i)} = \frac{(\underline{w}_1^{(i)})^T \underline{y}_d}{(\underline{w}_1^{(i)})^T \underline{w}_1^{(i)}}$$

$$\epsilon_{1i} = (h_1^{(i)})^2 \frac{(\underline{w}_1^{(i)})^T \underline{w}_1^{(i)}}{\underline{y}_d^T \underline{y}_d}$$

($1 \leq i \leq n$) where

$$\underline{x}_d = [x_d(t_1), \dots, x_d(t_n)]^T \text{ and}$$

$$\underline{y}_d = [y_d(t_1), \dots, y_d(t_n)]^T$$

are the input-output data set. Then, compute

$$\epsilon_1^{(i)} = \max\{\epsilon_1^{(i)} : 1 \leq i \leq n\}$$

and let

$$\underline{w}_1 = \underline{w}_1^{(i_1)} = \underline{g}_{i_1} \text{ and } h_1 = h_1^{(i_1)}.$$

Step 2. For each j , $2 \leq j \leq m_l$, compute

$$c_{kj}^{(i)} = \frac{\underline{w}_k^T \underline{g}_i}{\underline{w}_k^T \underline{w}_k}$$

$$\underline{w}_j^{(i)} = \underline{g}_i - \sum_{k=1}^{j-1} c_{kj}^{(i)} \underline{w}_k$$

$$h_j^{(i)} = \frac{(\underline{w}_j^{(i)})^T \underline{y}_d}{(\underline{w}_j^{(i)})^T \underline{w}_j^{(i)}}$$

$$\varepsilon_j^{(i)} = (h_j^{(i)})^2 \frac{(\underline{w}_j^{(i)})^T \underline{w}_j^{(i)}}{\underline{y}_d^T \underline{y}_d}$$

$$\varepsilon_k^{(i_j)} = \max \left\{ \varepsilon_j^{(i)} : 1 \leq i \leq n; i \neq i_1, \dots, i \neq i_{j-1} \right\}$$

where $\varepsilon_j^{(i)}$ represents the error-reduction ratio due to $\underline{w}_j^{(i)}$. Pick

$$\underline{w}_j = \underline{w}_j^{(i_j)} \text{ and } h_k = h_k^{(i_j)}.$$

Step 3. Solve equation

$$A^{(m_i)} \underline{\alpha}^{(m_i)} = \underline{h}^{(m_i)}$$

for a solution $\underline{\alpha}^{(m_i)} = [\alpha_1^{(m_i)}, \dots, \alpha_{m_i}^{(m_i)}]^T$,

where $\underline{h}^{(m_i)} = [h_1, \dots, h_{m_i}]^T$ and

$$A^{(m_i)} = \begin{bmatrix} 1 & c_{12}^{(i_2)} & c_{13}^{(i_3)} & \dots & c_{1m_i}^{(i_{m_i})} \\ 0 & 1 & c_{23}^{(i_3)} & \dots & c_{2m_i}^{(i_{m_i})} \\ \vdots & 0 & \ddots & & \vdots \\ 0 & & 0 & 1 & c_{m_i-1, m_i}^{(i_{m_i})} \\ 0 & 0 & \dots & 0 & 1 \end{bmatrix}$$

The final result is obtained as

$$f(\underline{x}) = \sum_{k=1}^{m_i} \alpha_k^{(m_i)} g_{i_k}(\underline{x})$$

An Approach Using Genetic Algorithms

The parameter identification procedure is generally very tedious for a large-scale complex system, for which the GA approach has some attractive features such as its great flexibility and robust optimization ability (Man, Tang, Kwong & Halang, 1997).

GA is attributed to Holland (1975), which was applied to fuzzy modeling and fuzzy control in the 1980s.

GA can be used to find an optimal or suboptimal fuzzy model to describe a given system without manual design (Joo, Hwang, Kim & Woo, 1997; Liska & Melsheimer, 1994; Soucek & Group, 1992). In addition, GA fuzzy modeling method can be integrated with other components of a fuzzy system, so as to achieve overall superior performance in control and automation.

Genetic Algorithm Preliminaries

GA provides an optimization method, with a stochastic search algorithm, based on some common biological principles of selection, crossover and mutation. A GA algorithm encodes each point in a solution space into a string composing of binary or real values, called a *chromosome*. Each point is assigned a fitness value from zero to one, which is usually taken to be the same as the objective function to be maximized. A GA scheme keeps a set of points as a *population*, which is evolved repeatedly toward a better and possibly the best fitness value. In each *generation*, GA generates a new population using genetic operators such as crossover and mutation. Through these operations, individuals with higher fitness values are more likely to survive and to participate in the next genetic operations. After a number of generations, individuals with higher fitness values are kept in the population while the others are eliminated. GA, therefore, can ensure a gradual increasing of improving solutions, till a desired optimal or suboptimal solution is obtained.

Basic GA Elements

A simple genetic algorithm (SGA) was first described by Goldberg (1989) and is used here for illustration, with a pseudo-code shown below, where the population at time t is a time function, $P = P(t)$, with a random initial population $P(0)$.

Procedure GA

Begin

$t = 0$

Initialize $P(t)$

Evaluate $P(t)$

While not finished do

Begin

$t = t + 1$

Reproduce $P(t)$ from $P(t-1)$

Crossover individuals in $P(t)$

```

Mutate individuals in  $P(t)$ 
Evaluate  $P(t)$ 
End
End

```

Population Representation and Initialization

Individuals are encoded as *strings* (i.e., chromosomes) composing of some alphabets, so that the *genotypes* (chromosome values) are uniquely mapped onto the decision variable (*phenotype*) domain. The most commonly used representation in GA is the binary alphabet, $\{0,1\}$; others are ternary, integer, real-valued, etc. (Takagi & Sugeno, 1985).

The search process, described below, will operate on these encoding decision variables rather than the decision variables themselves, except when real-valued genes are used. After a representation method has been chosen to use, the first step in the SGA is to create an initial population, by generating the required number of individuals via a random number generator which uniformly distributes initial numbers in the desired range.

Objective and Fitness Functions

The *objective function* is used to measure the performance of the individuals over the problem domain. The *fitness function* is used to transform the objective function value into a measure of relative fitness; mathematically, $F(x) = g(f(x))$, where f is the objective function, g is the transform that maps the value of f to a nonnegative number, and F is the resulting relative fitness. In general, the fitness function value corresponds to the number of offspring, and an individual can expect to produce this value in the next generation. A commonly used transform is the proportional fitness assignment, defined by

$$F(x_i) = f(x_i) / \sum_{i=1}^N f(x_i),$$

where N is the population size and x_i is the phenotypic value of individual i , $i = 1, \dots, N$.

Although the above fitness assignment ensures that each individual has a certain probability of reproduction according to its relative fitness, it does not account for negative objective function values. A linear transform, which offsets the objective function, is often used prior

to the fitness assignment. It takes the form

$$F(x) = fa(x) + b,$$

where a is a positive scaling factor if the optimization is to maximize the objective function but is negative if it is a minimization, and the offset b is used to ensure that the resulting fitness values are all negative.

Then, the selection algorithm selects individuals for reproduction on the basis of their relative fitness.

Reproduction

Once each individual has been assigned a fitness value, they can be chosen from the population with a probability according to their relative fitness. They can then be recombined to produce the next generation.

Most widely used genetic operators in GA are selection, crossover, and mutation operators. They are often run simultaneously in an GA program.

Selection

Selection is the process of determining the number of trials in which a particular individual is chosen for reproduction. Thus, it is the number of offspring that an individual will produce in the *mating pool*, a temporary population where crossover and mutation operations are applied to each individual. The selection of individuals has two separate processes:

- determination of the number of trials an individual can expect to receive;
- conversion of the expected number of trials into a discrete number of offspring.

Crossover (Recombination)

The crossover operator defines the procedure for generating children from two parents. Analogous to biological crossover, it exchanges genes at a randomly selected crossover point from also randomly selected parents in the mating pool to generate children.

A common method is the following: Parent chromosomes are cut at randomly selected points, which can be more than one, to exchange their genes at some specified crossover points with a user-specified crossover probability. This crossover method is categorized into single-point crossover and multi-point crossover

according to the number of crossover points. Uniform crossover often works well with small populations of chromosomes and for simpler problems (Soucek & Group, 1992).

Mutation

Mutation operation is randomly applied to individuals, so as to change their gene value with a mutation probability, P_m , which is very low in general.

GA Parameters

The choice of the mutation probability P_m and the crossover probability P_c as two control parameters can be a complex nonlinear optimization problem. Their settings are critically dependent upon the nature of the objective function. This selection issue still remains open to better resolutions. One suggestion is that for large population size (say 100), crossover rate is 0.6 and mutation rate is 0.001, while for small population size (such as 30), crossover rate is 0.9 and mutation rate is 0.01 (Zalzala & Fleming, 1997).

GA-Based Fuzzy System Modeling

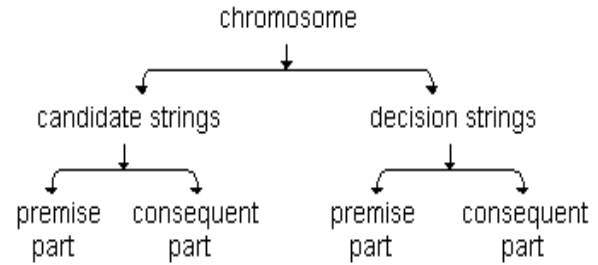

In GA, parameters for a given problem are represented by the chromosome. This chromosome may contain one or more substrings. Each chromosome contains a possible solution to the problem. Fitness function is used to evaluate how well a chromosome solves the problem. In the GA-based approach for fuzzy modeling, each chromosome represents a specific fuzzy model, and the ultimate goal is to carefully design a good (ideally optimal) chromosome to represent a desired fuzzy model.

Chromosome Structure

As an example, consider a simple fuzzy model with only one rule, along with the scatter partition to be encoded to a chromosome.

Suppose that both real number coding and integer number coding are used. The structure and the parameters of the fuzzy model are encoded into one or more substrings in the chromosome. A chromosome is composed of two substrings (candidate substring and decision substring) and these substrings are divided

Figure 2. A chromosome structure for fuzzy modeling

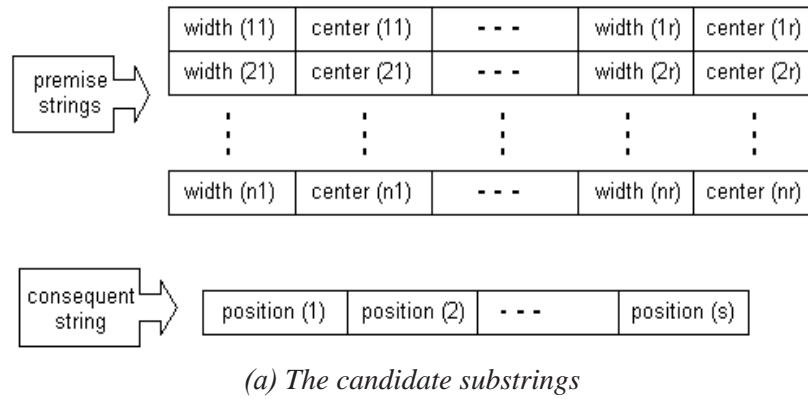

into two parts (IF part and THEN part), as shown in Fig. 2.

The candidate substring is encoded by real numbers, as shown in Fig. 3 (a). It contains the candidates for the parameters of a membership function in the IF part, and the fuzzy singleton membership function in the THEN part. Figure 3 describes the coding format of a candidate substring in a chromosome, where n is the number of input variables, r the number of candidates for parameters in the IF part, and s the number of candidates for the real numbers in the THEN part.

Decision substrings are encoded by integers, which determine the structure and the number of rules, by choosing one of the parameters in the candidate substrings, as illustrated by Fig. 3 (b).

The decision substrings for the IF part determine the premise structure of the fuzzy rule base. It is composed of n genes that take integer values (alleles) between 0 and r . According to this value, an appropriate parameter in the candidate substring is selected. A zero value means that the related input is not included in the rule. A decision substring for the THEN part is composed of c (the maximum number of rules) genes that take the integer values between 0 and s , which chooses appropriate values from the candidate substring for the THEN part. In this substring, the gene taking the zero value deletes the related rule. Therefore, these substrings determine the structure of the THEN part and the number of rules. Figure 4 illustrates an example of decoding the chromosome, with the resulting fuzzy rule shown in Fig. 5.

Figure 3. Two basic functions in a chromosome

Fitness Function

To measure the performance of the GA-based fuzzy modeling, an objective function is defined for optimization, which is chosen by the designer and usually is a least-squares matching measure of the form

$$J = \frac{1}{n} \sum_{i=1}^n (y_i - y_i^d)^2,$$

where $\{y_i\}$ and $\{y_i^d\}$ are the fuzzy model outputs and desired outputs, respectively, and n is the number of the data used.

Since GA is guided by the fitness values and requires literally no limit on the formulation of its performance measure, one can incorporate more information about a fuzzy model into the fitness function: $f = g(J_{structure}, J_{accuracy}, \dots)$. One example of a fitness function is

$$f(J) = \frac{\lambda}{J} + \frac{1-\lambda}{1+c},$$

where $\lambda \in [0, 1]$ is the weighting factor (a large λ gives a highly accurate model but requires a large number of rules), and c is the maximum number of rules. When the fitness function is evaluated over an empty set, it is

Figure 4. An example of genetic decoding process

Figure 5. The first fuzzy rule obtained by the decoding processes

undefined; but in this case one may introduce a penalty factor, $0 < p < 1$, and compute $p \cdot f(J)$ instead of $f(J)$. If an individual with a very high fitness value appears at the earlier stage, this fitness function may cause early convergence of the solution, thereby stopping the algorithm before optimality is reached. To avoid this situation, the individuals may be sorted according to their raw fitness values, and the new fitness values are determined recursively by

$$f_1 = 1, f_2 = fa_1 = a, \dots, f_m = a^m$$

for a fitness scaling factor $a \in (0, 1)$.

GA-Based Fuzzy Modeling with Fine Tuning

GA generally does not guarantee the convergence to a global optimum. In order to improve this, the gradient descent method can be used to fine tune the parameters

identified by GA. Since GA usually can find a near global optimum, to this end fine tuning of the membership function parameters in both IF and THEN parts, e.g., by a gradient descent method, can generally lead to a global optimization (Chang, Joo, Park & Chen, 2002; Goldberg, 1989).

FUTURE TRENDS

This will be further discussed elsewhere in the future.

CONCLUSION

Fuzzy systems identification is an important and yet challenging subject for research, which calls for more efforts from the control theory and intelligent systems communities, to reach another high level of efficiency and success.

KEY TERMS

Fuzzy Rule: A logical rule established based on fuzzy logic.

Fuzzy System: A system formulated and described by fuzzy set-based real-valued functions.

Genetic Algorithm: An optimization scheme based on biological genetic evolutionary principles.

Least-Squares Algorithm: An optimization scheme that minimizes the square of the sum of the approximation errors.

Parameter Identification: Find appropriate parameter values in a mathematical model.

Structure Identification: Find a mathematical representation of the unknown system's structure.

System Modeling: A mathematical formulation of an unknown physical system or process.

Gene Regulation Network Use for Information Processing

J. Andrés Serantes

University of A Coruña, Spain

INTRODUCTION

From the unicellular to the more complex pluricellular organism needs to process the signals from its environment to survive. The computation science has already observed, that fact could be demonstrated remembering the artificial neural networks (ANN). This computation tool is based on the nervous system of the animals, but not only the nervous cells process information in an organism. Every cell has to process the development and functioning plan encoded at its DNA and every one of these cells executes this program in parallel with the others. Another interesting characteristic of natural cells is that they form systems that are tolerant to partial failures: small errors do not induce a global collapse of the system.

The present work proposes a model that is based on DNA information processing, but adapting it to general information processing. This model can be based on a set of techniques called Artificial Embryogeny (Stanley K. & Miikkulainen R. 2003) which adapts characteristics from the biological cells to solve different problems.

BACKGROUND

The Evolutionary Computation (EC) field has given rise to a set of models that are grouped under the name of Artificial Embryology (AE), first introduced by Stanley and Miikkulainen (Stanley K. & Miikkulainen R. 2003). This group refers to all the models that try to apply certain characteristics of biological embryonic cells to computer problem solving, i.e. self-organisation, failure tolerance, and parallel information processing.

The work on AE has two points of view. On the one hand can be found the grammatical models based on L-systems (Lindenmayer A. 1968) which do a top-down

approach to the problem. On the other hand can be found the chemical models based on the Turing's ideas (Turing A. 1952) which do a down-top approach.

The grammatically approach, some times, has used the models for study the evolution of ANN, which is known as neuroevolution. The first neuroevolution system was development by Kitano (Kitano, H. 1990). In this work Kitano shows that it was possible to evolve the connectivity matrix of ANN through a set of rewrite rules. Another remarkable work is the application of L-systems do by Hornby and Pollack (Hornby, G. S. & Pollack J. B. 2002). At this work they simultaneously evolved the body morphologies and the neural network of artificial creatures in a simulated 3D physical environment. Finally, mention the works carry out by Gruau (Gruau F. 1994) where the author uses grammar trees to encode steps in the development of a neural network from a single antecesor cell.

On the chemical approach, the starting point of this field can be found in the modelling of gene regulatory networks, performed by Kauffman in 1969 (Kauffman S.A. 1969). After that, several works were carried out on subjects such as the complex behaviour generated by the fact that the differential expression of certain genes has a cascade influence on the expressions of others (Mjolsness E., Sharp D.H., & Reinitz J. 1995). Considering the gene regulatory networks works, the most relevant models are the following: the Kumar and Bentley model (Kumar S. & Bentley P.J. 2003), which uses the theory of fractal proteins Bentley, P.J., Kumar, S. 1999; for the calculation of protein concentration; the Eggenberger model (Eggenberger P. 1996), which uses the concepts of cellular differentiation and cellular movement to determine cell connections; and the work of Dellaert and Beer (Dellaert F. & Beer R.D. 1996), who propose a model that incorporates the idea of biological operons to control the model expression, where the function assumes the mathematical meaning of a Boolean function.

GENETIC REGULATORY NETWORK MODEL

The cells of a biological system are mainly determined by the DNA strand, the genes, and the proteins contained by the cytoplasm. The DNA is the structure that holds the gene-encoded information that is needed for the development of the system. The genes are activated or transcribed thanks to the protein shaped-information that exists in the cytoplasm, and consist of two main parts: the sequence, which identifies the protein that will be generated if the gene is transcribed, and the promoter, which identifies the proteins that are needed for gene transcription.

Another remarkable aspect of biological genes is the difference between constitutive genes and regulating genes. The latter are transcribed only when the proteins identified in the promoter part are present. The constitutive genes are always transcribed, unless inhibited by the presence of the proteins identified in the promoter part, acting then as gene oppressors.

The present work has tried to partially model this structure with the aim of fitting some of its abilities into a computational model; in this way, the system would have a structure similar that is similar to the above and will be detailed in the next section.

Proposed Model

Various model variants were developed on the basis of biological concepts. The proposed artificial cellular system is based on the interaction of artificial cells by means of messages that are called proteins. These cells can divide themselves, die, or generate proteins

that will act as messages for themselves as well as for neighbour cells.

The system is supposed to express a global behaviour towards the information processing. Such behaviour would emerge from the information encoded in a set of variables of the cell that, in analogy with the biological cells, will be named genes.

The central element of our model is the artificial cell. Every cell has a binary string-encoded information for the regulation of its functioning. Following the biological analogy, this string will be called DNA. The cell also has a structure for the storage and management of the proteins generated by the own cell and those received from neighbourhood cells; following the biological model, this structure is called cytoplasm.

The DNA of the artificial cell consists of functional units that are called genes. Each gene encodes a protein or message (produced by the gene). The structure of a gene has four parts (see **Figure 1**):

- Sequence: the binary string that corresponds to the protein that encodes the gene
- Promoters: is the gene area that indicates the proteins that are needed for the gene’s transcription.
- Constituent: this bit identifies if the gene is constituent or regulating
- Activation percentage (binary value): the percentage of minimal concentration of promoters proteins inside the cell that causes the transcription of the gene.

The transcription of the encoded protein occurs when the promoters of the non-constituent genes appear in a certain rate at the cellular cytoplasm. On the other hand, the constituent genes are expressed until such expression is inhibited by the present rate of the promoter genes.

The other fundamental element for keeping and managing the proteins that are received or produced by the artificial cell is the cytoplasm. The stored proteins have a certain life time before they are erased. The cytoplasm checks which and how many proteins are needed for the cell to activate the DNA genes, and as such responds to all the cellular requirements for the concentration of a given type of protein. The cytoplasm also extracts the proteins from the structure in case they are needed for a gene transcription.

Figure 1. Structure of a system gene

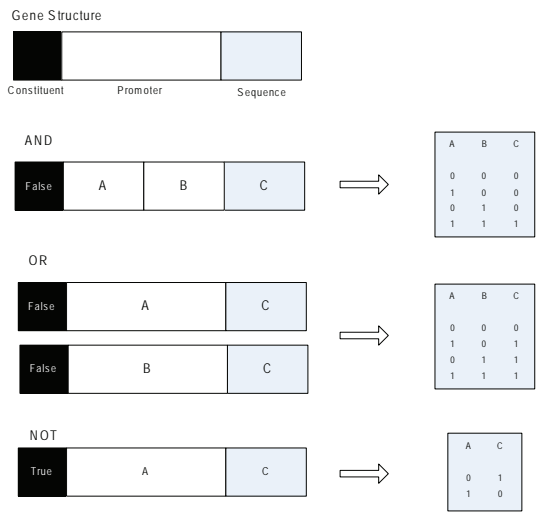

Figure 2. Logical operators match

The Information Processing Capacities

The biological cells, besides generating structures, work as small processors for parallel information handling with the remaining cells. The information that they process comes from their own generation and from their environment. On the basis of this fact, the present work has explored the generation capabilities of the model structure, although using the gene and protein structure, an operation set with Boolean algebra-like structure might be defined.

The space for the definition of the operations would be the presence or absence of certain proteins into the system, whereas the operation result would be the protein contained/encoded at the gene. The AND operation (see Figure 2) would be modelled with a gene that would need for its expression all the proteins of its promoters. The OR operation would be modelled with two genes that, despite their different promoters, result in the same protein. Finally, the NOT operation would be modelled with the constituent part, which changes the performance of that gene. The presence of proteins belonging to the promoters would imply the absence of the gene resulting protein at the system. This behaviour is similar to the gene regulatory networks (Kauffman S.A. 1969).

The Artificial Neuron Networks (ANNs) can be configured for carrying out these processing tasks.

This analogous functioning seems to indicate that the system could execute more complex tasks, as ANNs do (Hassoun M.H. 1995).

FUTURE TRENDS

The final objective of this group is to develop an artificial model which is based on the biologically model with a processing information capacity similar to the ANN. In order to archive this objective some simple tests have been developed to check the functioning of the model. The result of these tests show that is possible to process information using the gene regulatory network as the basing system.

From this point of development, the next steps of development must go in order to develop more complex task and to study the functioning of the model. Other objective for future works can be the combination of the process information capacities of the model with the generating structure capacities presented in (Fernández-Blanco E., Dorado J., Rabuñal J.R., Gestal M. & Pedreira N. 2007).

CONCLUSION

At this work some properties of biological cells have been adapted to an artificial model. In particular the gene regulatory network idea was adapted to processing information. This adaptation has its bases on using the transcription rule to determine a boolean algebra like structure. The result of this adaptation is that, now, we can use it to develop processing information tests and.

Finally comment that this new way of generation processing information networks has a lot of test and studies to do until it is stabilized as a consolidated technique for information processing.

KEY TERMS

Artificial Cell: Each of the elements that process the orders codified into the DNA.

Artificial Embryogeny: Under this term are all the processing models which use biological development ideas as inspiration.

Cytoplasm: Part of an artificial cell which is responsible of management the protein-shaped messages.

DNA: Set of rules which are responsible of the cell behaviour.

Gene: Each of the rules which codifies one action of the cell.

Gene Regulatory Network: Term that names the connexion between the different genes of a DNA. The connexion identifies the genes that are necessary for the transcription of other ones.

Protein: This term identifies every kind of the messages that receives an artificial cell.

Genetic Algorithm Applications to Optimization Modeling

Pi-Sheng Deng

California State University at Stanislaus, USA

INTRODUCTION

Genetic algorithms (GAs) are stochastic search techniques based on the concepts of natural population genetics for exploring a huge solution space in identifying optimal or near optimal solutions (Davis, 1991)(Holland, 1992)(Reeves & Rowe, 2003), and are more likely able to avoid the local optima problem than traditional gradient based hill-climbing optimization techniques when solving complex problems.

In essence, GAs are a type of reinforcement learning technique (Grefenstette, 1993), which are able to improve solutions gradually on the basis of the previous solutions. GAs are characterized by their abilities to combine candidate solutions to exploit efficiently a promising area in the solution space while stochastically exploring new search regions with expected improved performance. Many successful applications of this technique are frequently reported across various kinds of industries and businesses, including function optimization (Ballester & Carter, 2004)(Richter & Paxton, 2005), financial risk and portfolio management (Shin & Han, 1999), market trading (Kean, 1995), machine vision and pattern recognition (Vafaie & De Jong, 1998), document retrieval (Gordon, 1988), network topological design (Pierre & Legault, 1998)(Arabas & Kozdrowski, 2001), job shop scheduling (Özdamar, 1999), and optimization for operating system's dynamic memory configuration (Del Rosso, 2006), among others.

In this research we introduce the concept and components of GAs, and then apply the GA technique to the modeling of the batch selection problem of flexible manufacturing systems (FMSs). The model developed in this paper serves as the basis for the experiment in Deng (2007).

GENETIC ALGORITHMS

GAs were simulation techniques proposed by John Holland in the 1960s (Holland, 1992). Basically, GAs

solve problems by maintaining and modifying a population of candidate solutions through the application of genetic operators. During this process, beneficial changes to parent solutions are combined into their offspring in developing optimal or near-optimal solutions for the given task.

Intrinsically, GAs explore multiple potentially promising regions in the solution space at the same time, and switch stochastically from one region to another for performance improvement. According to Holland (1992), regions in the solution space can be defined by syntactic patterns of solutions, and each pattern is called a schema. A schema represents the pattern of common attributes or features of the solutions in the same region. Let Σ be an alphabet of symbols. A string over an alphabet is a finite sequence of symbols from the alphabet. An n -ary schema is defined as a string in $(\Sigma \cup \{\#\})^n$, where $\# \notin \Sigma$ is used as a wildcard denotation for any symbol in Σ .

Conceptually, n -ary schemata can be regarded as defining hypersurfaces of an n -dimensional hypercube that represents the space of all n -attribute solutions. Individual solutions in the same region can be regarded as instances of the representing schema, and an individual solution can belong to multiple schemata at the same time. Actually, an n -attribute solution is a member of 2^n different schemata. Therefore, evaluating a solution has the similar effect of sampling 2^n regions (i.e., schemata) at the same time, and this is the famous implicit parallelism of genetic search. A population of M solutions will contain at least 2^n and at most $M \cdot 2^n$ schemata. Even for modest values of n and M , there will be a large number of schemata available for processing in the population. GAs perform an implicit parallel search through the space of possible schemata in the form of performing an explicit parallel search through the space of individual solutions.

The problem solving process of GAs follows a five-phase operational cycle: generation, evaluation, selection, recombination (or crossover), and mutation.

At first a population of candidate solutions is generated. A fitness function or objective function is then defined, and each candidate solution in the population is evaluated to determine its performance or fitness. Based on the relative fitness value, two candidate solutions are selected probabilistically as parents. Recombination is then applied probabilistically to the two parents to form two offspring, and each of the offspring solutions contains some characteristics from its parent solutions. After this, mutation is applied sparingly to components of each offspring solution. The newly generated offspring are then used to replace the low-fitness members in the population. This process is repeated until a new population is formed. Through the above iterative cycles of operations, GAs is able to develop better solutions through progressive generations.

In order to prepare for the investigation of the effects of genetic operations in the sequel of current research, we apply the GA technique to the optimization modeling of manufacturing systems in next section.

A GA-BASED BATCH SELECTION SYSTEM

Batch selection is one of the most critical tasks in the development of a master production plan for flexible manufacturing systems (FMSs). In the manufacturing process, each product requires processing by different sets of tools on different machines with different operations performed in a certain sequence. Each machine has its own limited space capacity in mounting tools and limited amount of available processing time. Under various kinds of resource constraints, choosing an optimal batch of products to be manufactured in a continuous operational process with the purpose to maximize machine utilization or profits has made the batch selection decision a very hard problem. While this problem is usually manageable for manufacturing small number of products, it quickly becomes intractable if the number of products grows even slightly large. The time required to solve the problem exhaustively would grow in a non-deterministic polynomial manner with the number of products to be manufactured.

Batch selection affects all the subsequent decisions in job shop scheduling for satisfying the master production plan, and holds the key to the efficient utilization of resources in generating production plans

for fulfilling production orders. In our formulation, we use the following denotational symbols:

- M : the cardinality of the the set of machines available
- T : the cardinality of the the set of tools available
- P : the cardinality of the set of products to be manufactured
- $MachineUtilization$: the function of total machine utilization
- $processing_time_{product,tool,machine}$: the time needed to manufacture product $product$ using tool $tool$ on machine $machine$
- $available_time_{machine}$: the total available processing time on machine $machine$
- $capacity_{machine}$: the total number of slots available on machine $machine$
- $machine, tool, product$: indicators for machines, tools, and products to be manufactured correspondingly
- $slot_{tool}$: the number of slot required by machine tool $tool$
- $quantity_{product}$: the quantity of product $product$ to be manufactured in a shift
- $Q_{product}$: the quantity of product $product$ ordered by customers as specified in the production table

Fitness (or Objective) Function

The objective is to identify a batch of products to be manufactured so that the total machine utilization rate will be maximized. See Exhibit A.

The above objective function is to be maximized subject to the following resource constraints:

1. Machine capacity constraint (see Exhibit B)

The above function $f(\bullet)$ is used to determine if tool $tool$ needs to be mounted on machine $machine$ for the processing of the current batch of product.

2. Machine time constraint (see Exhibit C)
3. Non-negativity and integer constraints

Encoder/Decoder

The Encoder/Decoder is a representation scheme used to determine how the problem is structured in the GA

Exhibit A.

$$\begin{aligned} \text{Maximize} \quad & \text{MachineUtilization}(\text{quantity}_1, \text{quantity}_2, \dots, \text{quantity}_P) = \\ & \frac{\sum_{\text{machine}=1}^M \sum_{\text{tool}=1}^T \sum_{\text{product}=1}^P \text{processing_time}_{\text{product,tool,machine}} \text{quantity}_{\text{product}}}{\sum_{\text{machine}=1}^M \text{available_time}_{\text{machine}}} \end{aligned}$$

Exhibit B.

$$\begin{aligned} \sum_{\text{tool}=1}^T \text{slot}_{\text{tool}} f\left(\sum_{\text{product}=1}^P \text{processing_time}_{\text{product,tool,1}} \text{quantity}_{\text{product}}\right) &\leq \text{capacity}_1 \\ \vdots \\ \sum_{\text{tool}=1}^T \text{slot}_{\text{tool}} f\left(\sum_{\text{product}=1}^P \text{processing_time}_{\text{product,tool,M}} \text{quantity}_{\text{product}}\right) &\leq \text{capacity}_M \end{aligned}$$

where $f(y) = \begin{cases} 1, & \text{if } y > 0 \\ 0, & \text{if } y = 0 \end{cases}$

Exhibit C.

$$\begin{aligned} \sum_{\text{product}=1}^P \sum_{\text{tool}=1}^T \text{processing_time}_{\text{product,tool,1}} \text{quantity}_{\text{product}} &\leq \text{available_time}_1 \\ \vdots \\ \sum_{\text{product}=1}^P \sum_{\text{tool}=1}^T \text{processing_time}_{\text{product,tool,M}} \text{quantity}_{\text{product}} &\leq \text{available_time}_M \end{aligned}$$

$$\begin{aligned} \text{quantity}_{\text{product}} &\geq 0, \\ \text{quantity}_{\text{product}} &\leq Q_{\text{product}}, \text{ and} \\ \text{quantity}_{\text{product}} &\text{ is an integer, for } \text{product} = 1, 2, \dots, P \end{aligned}$$

system. The way in which candidate solutions are encoded is one of a central factor in the success of GAs (Mitchell, 1996). Generally, the solution encoding can be defined over an alphabet Σ which might consist of binary digits, continuous numbers, integers, or symbols. However, choosing the best encoding scheme is almost tantamount to solving the problem itself (Mitchell, 1996). In this research, our GA system is mainly based on Holland's canonical model (Holland, 1992), which

is one of the most commonly used encoding schemes in practice—binary encoding.

A candidate solution for the batch selection task is a vector of quantities to be manufactured for P products. Let the entire solution space be denoted as **solution** (see Exhibit D).

The encoding function encodes the quantity to be produced for each product as an l -bit binary string, and then forms a concatenation of the strings for P products

Exhibit D.

$$\begin{aligned}
\text{solution} &= \prod_{product=1}^P [0, 1, \dots, Q_{product}] \\
&= \{ \text{quantity}_1, \dots, \text{quantity}_P \} \in (\{0\} \cup \mathbb{N})^P \mid 0 \leq \text{quantity}_{product} \leq Q_{product}, \\
&\quad \text{quantity}_{product} \text{ is an integer, and } product = 1, 2, \dots, P\}
\end{aligned}$$

which are to be included in a production batch. Each candidate solution $(\text{quantity}_1, \dots, \text{quantity}_P)$ is a string of length lP over the binary alphabet $\Sigma = \{0, 1\}$. Such an encoded l -bit string has a value equal to

$$\begin{cases} \text{quantity}_{product}, & \text{if } \max_{product=1,2,\dots,P} \{Q_{product}\} \leq 2^l - 1 \\ \left\lceil \frac{\text{quantity}_{product} (2^l - 1)}{\max_{product=1,2,\dots,P} \{Q_{product}\}} - 0.5 \right\rceil, & \text{otherwise.} \end{cases}$$

In the above formula, $2^l - 1$ is the value of an l -

bit string $\underbrace{1 \dots 1}_l$, and $\lceil \bullet \rceil$ is the ceiling function. For example, assume there are only two products to be selected in a production batch with 200 units as the largest possible quantity to be manufactured for each product. A candidate solution consisting of quantities 100 and 51 for products 1 and 2 respectively will be represented by a 16-bit string as 0110010000110011 with the first 8 bits representing product 1 and the second 8 bits representing product 2.

After a new solution string is generated, it is then decoded back to the format for the computation of the objective function and for the check of solution feasibility. Let each l -bit segment of a solution string be denoted as $string$ with $string[i]$ as the value of the i^{th} bit in the l -bit segment. The decoding function converts each l -bit string according to the following formula:

$$\begin{cases} \sum_{i=1}^l string[i] \cdot 2^{i-1}, & \text{if } \max_{product=1,2,\dots,P} \{Q_{product}\} \leq 2^l - 1 \\ \left\lceil \left(\sum_{i=1}^l string[i] \cdot 2^{i-1} \right) \cdot \frac{\max_{product=1,2,\dots,P} \{Q_{product}\}}{2^l - 1} - 0.5 \right\rceil, & \text{otherwise.} \end{cases}$$

Five-Phase Genetic Operations

Our system follows the generation-evaluation-selection-crossover-mutation cycles in searching for appropriate solution strings for the batch selection task. It starts with generating an initial population, **Pop**, of pop_size candidate solution strings at random. In each iteration of the operational cycle, each candidate solution string, s_i , in the current population is evaluated by the fitness function.

Candidate solution strings in the current population are selected probabilistically on the basis of their fitness values as seeds for generating the next generation. The purpose of selection is to generate offspring of high fitness value on the basis of the fitter members in the current population. Actually, selection is the mechanism that helps our GA system to exploit a promising region in the solution space. There are several fitness-based schemes for the selection process: Roulette-wheel selection, rank-based selection, tournament selection, and elitist selection (Goldberg, 1989)(Michalewicz, 1994). The first three methods randomly select candidate solution strings for reproduction on the basis of either the fitness value or the rank of individual strings. Best members of the current population might be lost if they are not selected to reproduce or if they are altered by crossover (i.e., recombination) or mutation. The elitist selection strategy is for the purpose of retaining some of the fittest individuals from the current population.

Elitist selection retains a limited number of “elite” solution strings, i.e., strings with the best fitness

values, for passing to the next generation without any modification. A fraction called the “generation gap” is used to specify the proportion of the population to be replaced by offspring strings after each iteration. Our GA system retains copies of the first $(1 - \text{generation_gap}) \cdot \text{pop_size}$ “elitist” members of **Pop** for the formation of the next population, **Pop_{new}**.

For generating the rest of the members for **Pop_{new}**, the GA module will probabilistically select:

$$\frac{\text{generation_gap} \cdot \text{pop_size}}{2}$$

pairs of solution strings from **Pop** for generating offspring strings. The probability of selecting a solution string, s_i , from **Pop** is given by

$$\Pr(s_i) = \frac{\text{Fitness}(s_i)}{\sum_{j=1}^{\text{pop_size}} \text{Fitness}(s_j)}$$

Let the cumulative probability of individual solution strings in the population be called C_i , and

$$C_i = \sum_{j=1}^i \Pr(s_j),$$

for $i = 1, 2, \dots, \text{pop_size}$. The solution string s_i will be selected for reproduction if $C_{i-1} < \text{rand}(0,1) \leq C_i$.

In addition to exploiting a promising solution region via the selection process, we also need to explore other promising regions for possible better solutions. Exploitation without exploration will cause degeneration for a population of solution strings, and might cause the local optima problem for the system. Actually, the capability of maintaining a balanced exploitation vs. exploration is a major strength of the GA approach over traditional optimization techniques. The exploration function is achieved by the crossover and mutation operators. These two operators generate offspring solutions which belong to new schemata, and thus allow our system to explore other promising regions in a solution space. This process also allows our system to improve its performance stochastically.

Crossover recombines good solution strings in the current population and proliferates the population gradually with schemata of high fitness values. Crossover is commonly regarded as the most distinguishing operator of GAs, and it usually interacts in a highly intractable manner with fitness function, encoding, and other details of a GA (Mitchell, 1996). Though various crossover operators have been proposed, there is no general conclusions on when to use which type of crossover (Michalewicz, 1994)(Mitchell, 1996).

In this paper, we adopt the standard one-point crossover for our GA system. For each pair of solution strings selected for reproduction, the value of *crossover_rate* determines the probability for their recombination. A position in both candidate solution strings is randomly selected as the crossover point. The parts of two parent strings after the crossover position are exchanged to form two offspring. Let k be the crossover point randomly generated from a uniform distribution ranging from 1 to l_P , where l_P is the length of a solution string. Let $s_i = (x_1, x_2, \dots, x_{k-1}, x_k, \dots, x_{l_P})$ and $s_j = (y_1, y_2, \dots, y_{k-1}, y_k, \dots, y_{l_P})$ represent a pair of candidate solution strings selected for reproduction. Based on these two strings, the crossover operator generates two offspring $s'_i = (x'_1, x'_2, \dots, x'_{l_P})$ and $s'_j = (y'_1, y'_2, \dots, y'_{l_P})$, where

$$x'_i = \begin{cases} x_i, & \text{if } i < k \\ y_i, & \text{otherwise} \end{cases}$$

$$y'_i = \begin{cases} y_i, & \text{if } i < k \\ x_i, & \text{otherwise.} \end{cases}$$

In other words, $s'_i = (x_1, x_2, \dots, x_{k-1}, y_k, \dots, y_{l_P})$ and $s'_j = (y_1, y_2, \dots, y_{k-1}, x_k, \dots, x_{l_P})$. These two offspring are then added to **Pop_{new}**. This offspring-generating process is repeated until there are $\text{generation_gap} \cdot \text{pop_size}$ offspring generated for **Pop_{new}**.

With selection and crossover alone, our system might occasionally develop a uniform population which consists of the same solution strings. This will blind our system to other possible solutions. Mutation, which is the other operator applied to the reproduction process, is used to help our system avoid the formation of a uniform population by introducing diversity into a population. It is generally believed that mutation alone does not advance the search for a solution, and is usu-

ally considered as a secondary role in the operation of GAs (Goldberg, 1989). Usually, mutation is applied to alter the bit value of a string in a population only occasionally. Let *mutation_rate* be the probability of mutation for each bit in a candidate solution string.

For each offspring string, $s' = (x'_1, x'_2, \dots, x'_{lp})$, generated by the crossover operator for the new population *Pop_{new}*, the mutation operator will invert each bit probabilistically:

$$x'_i = \begin{cases} 1 - x_i, & \text{if } \text{rand}(0,1) < \text{mutation_rate} \\ x_i, & \text{otherwise.} \end{cases}$$

The probability of mutation for a candidate solution string is $1 - (1 - \text{mutation_rate})^{lp}$.

The above processes constitute an operational cycle of our system. These operations are repeated until the termination criterion is reached, and the result is passed to the Decoder for decoding. The decoded result is then presented to the decision maker for further consideration in the final decision. If current solution is not satisfactory to the decision maker, the current solution can be modified by the decision maker, and then entered into the GA system to initiate another run of search process for satisfactory solutions.

FUTURE TRENDS AND CONCLUSION

In this paper we designed a GA-based system for the batch selection problem of flexible manufacturing systems. In our design we adopted a binary encoding scheme, the elitist selection strategy, a single-point crossover strategy, and a uniform random mutation for the batch selection problem.

The performance of GAs is usually influenced by various parameters and the complicated interactions among them, and there are several issues worth further investigation. With the availability of a larger pool of diverse schemata in a larger population, our GA system will have a broader view of the “landscape” (Holland, 1992) of the solution space, and is thus more likely to contain representative solutions from a large number of hyperplanes. This advantage gives GAs more chances of discovering better solutions in the solution space. However, Davis (1991) argues that the most effective population size is dependent upon the nature of the problem, the representation formalism, and the GA

operators. Still, Schaffer *et al.* (1991) asserted that the best settings for population size is independent of the problems. In the sequel of this paper, we will conduct a sequence of experiment to systematically analyze the influence of the population size on GA performance, by using the batch-selection model proposed in this paper, so that we can be more conclusive on the issue of the effective population size.

Batch Selection: Selecting the optimal set of products to produce, with each product requiring a set of resources, under the system capacity constraints

Fitness Functions: The objective function of the GA for evaluating a population of solutions

Flexible Manufacturing Systems: A manufacturing system which maintains the flexibility of order of operations and machine assignment in reacting to planned or unplanned changes in the production process

Genetic Algorithms: A stochastic search method which applies genetic operators to a population of solutions for progressively generating optimal or near-optimal solutions

Genetic Operators: Selection, crossover, and mutation, for combining and refining solutions in a population

Implicit Parallelism: A property of the GA which allows a schema to be matched by multiple candidate solutions simultaneously without even trying

Landscape: A function plot showing the state as the “location” and the objective function value as the “elevation”

Reinforcement Learning: A learning method which interprets feedback from an environment to learn optimal sets of condition/response relationships for problem solving within that environment

Schemata: A general pattern of bit strings that is made up of 1, 0, and #, used as a building block for solutions of the GA

Genetic Algorithms for Wireless Sensor Networks

João H. Kleinschmidt

State University of Campinas, Brazil

INTRODUCTION

Wireless sensor networks (WSNs) consist of a large number of low-cost and low-power sensor nodes. Some of the applications of sensor networks are environmental observation, monitoring disaster areas and so on. Distributed evolutionary computing is a powerful tool that can be applied to WSNs, because these networks require algorithms that are capable of learning independent of the operation of other nodes and also capable of using local information (Johnson, Teredesai & Saltarelli, 2005). Evolutionary algorithms must be designed for the resource constraints present in WSNs. This article describes how genetic algorithms can be used in WSNs design in order to satisfy energy conservation and connectivity constraints.

BACKGROUND

The recent advances in wireless communications and digital electronics led to the implementation of low power and low cost wireless sensors. A sensor node must have components for sensing, data processing and communication. These devices can be grouped to form a sensor network (Akyildiz, Sankarasubramanian & Cayirci, 2002) (Callaway 2003). The network protocols, such as formation algorithms, routing and management, must have self-organizing capabilities. In

general, sensor networks have some features that differ from traditional wireless networks in some aspects: the number of sensor nodes can be very high; sensor nodes are prone to failures; sensor nodes are densely deployed; the topology of the network can change frequently; sensor nodes are limited in computational capacities, memory and energy.

The major challenge in the design of WSNs is the fact that energy resources are significantly more limited than in wired networks and other types of wireless networks. The battery of the sensors in the network may be difficult to recharge or replace, causing severe limitations in the communication and processing time between all sensors in the network. Thus, the main parameter to optimize for is the network lifetime, or the time until a group of sensors runs out of energy. Another issue in WSN design is the connectivity of the network according to the selected communication protocol. Usually, the protocol follows the cluster-based architecture, where single hop communication occurs between sensors of a cluster and a selected cluster head sensor that collects all information obtained by the other sensors in its cluster. This architecture is shown in Figure 1. Since the purpose of the sensor network is the collection and management of measured data for some particular application, this collection must meet specific requirements depending on the type of data. These requirements are turned into application specific parameters of the network.

Figure 1. Cluster-based sensor network

GENETIC ALGORITHMS FOR WIRELESS SENSOR NETWORKS

A WSN designer who takes into account all the design issues deals with more than one non-linear objective functions or design criteria which should be optimized simultaneously. Therefore, the focus of the problem is how to find many near-optimal non-dominated solutions in a practically acceptable computational time (Jourdan & de Weck, 2004) (Weise, 2006) (Ferentinos & Tsiligiridis, 2007). There are several interesting approaches to tackling such problems, but one of the most powerful heuristics, which is also appropriate to apply in the multi-objective optimization problem, is based on genetic algorithms (GA) (Ferentinos & Tsiligiridis, 2007).

Genetic algorithms have been used in many fields of science to derive solutions for any type of problems (Goldberg 1989) (Weise, 2006). They are particularly useful in applications involving design and optimization, where there are large numbers of variables and where procedural algorithms are either non-existent or extremely complicated (Khana, Liu & Chen, 2006), (Khana, Liu & Chen, 2007). In nature, a species adapts to an environment because the individuals that are the fittest in respect to that environment will have the best chance to reproduce, possibly creating even fitter child. This is the basic idea of genetic evolution. Genetic algorithms start with an initial population of random solution candidates, called individuals or chromosomes. In the case of sensor networks, the individuals are small programs that can be executed on sensor nodes (Wazed, Bari, Jaekel & Bandyopadhyay, 2007).

Each individual may be represented as a simple string or array of genes, which contain a part of the solution. The values of genes are called alleles. As in nature, the population will be refined step by step in a cycle of computing the fitness of its individuals, selecting the best individuals and creating a new generation derived from these. A fitness function is provided to assign the fitness value for each individual, based on how close an individual is to the optimal solution. Two randomly selected individuals, the parents, can exchange genetic information in a process called crossover to produce two new chromosomes known as child. A process called mutation may also be applied to obtain a good solution, after the process of crossover. This process helps to restore any genetic values when the population converges

too fast. After the crossover and mutation processes the individuals of the next generation are selected. Some of the poorest individuals of the generation can be replaced by the best individuals from the previous generation. This is called elitism, and ensures that the new generation is at least as fit as the previous generation. The algorithm stops if a predetermined stopping criterion is met (Hussain, Matin & Islam, 2007).

Fitness Function and Specific Parameters for WSNs

The fitness function executed in a sensor node is a weighted function that measures the quality or performance of a solution, in this case a specific sensor network design. This function is maximized by the GA system in the process of evolutionary optimization. A fitness function must include and correctly represent all or at least the most important factors that affect the performance of the system. The major issue in developing a fitness function is the decision on which factors are the most important ones (Ferentinos & Tsiligiridis, 2007) (Gnanapandithan & Natarajan, 2006).

A genetic algorithm must be designed for WSN topologies by optimizing energy-related parameters that affect the battery consumption of the sensors and thus, the lifetime of the network. At the same time, the algorithm has to meet some connectivity constraints and optimize some physical parameters of the WSN implemented by the specific application. The multiple objectives of the optimization problem are blended into a single objective function, the parameters of which are combined to formulate a fitness function that gives a quality measure to each WSN topology. Three sets of parameters dominate the design and the performance of a WSN: the application specific parameters, connectivity parameters and the energy related parameters. Some possible parameters are discussed in (Ferentinos & Tsiligiridis, 2007):

- Operation energy: the energy that a sensor consumes during some specific time of operation. It depends whether the sensor operates as cluster head or as regular sensor.
- Communication energy: the energy consumption due to communication between sensors. It depends on the distances between transmitter and receiver.

- Battery life: battery capacity of each sensor.
- Sensors-per-cluster head: parameter to ensure that each cluster head does not have more than a maximum predefined number of sensors in its cluster. It depends on the physical communications capabilities and the amount of data that can be processed by a cluster head.
- Sensors out of range error: parameter to ensure that each sensor can communicate with its cluster head. It depends on the signal strength of the sensors.
- Spatial density: minimal number of measurements points that adequately monitor the variables of a given area.
- Uniformity of measurement: the measures of an area of interest must give a uniform view of the area conditions. The total area can be divided into several sub-areas for a uniform measurement.

Other parameters can be defined, especially those related to application specific requirements, such as sensor to sink delay, routing information, localization, network coverage, etc. The optimization problem is defined by the minimization of the WSN parameters. If n optimization parameters were defined, they may be combined into a single objective function:

$$f = \min \left\{ \sum_{i=1}^n w_i P_i \right\},$$

where P is the parameter objective and w is the weighting coefficients, that define the importance of each parameter in the network design. The importance of each parameter on the performance of the network has to be designed carefully. These values are firstly determined based on experience on the importance of each one. Then, some experimentation is made to determine the final values. An individual will be selected to be the parent of the next generation using its fitness value. The probability that an individual be chosen is proportional to the value. After this process, the type of crossover and mutation has to be defined, as well as the population size and the probabilities for crossover and mutation. Some experiments must be carried out to determine the most appropriate values for WSNs.

FUTURE TRENDS

Some of the recent research areas in wireless sensor networks include the design of MAC protocols, efficient routing, data aggregation, collaborative processing, sensor fusion, security, localization, data reliability, network management, etc. All these topics may benefit from the usage of genetic algorithms. Some research has been made using genetic algorithms to solve some WSNs problems (Hussain, Matin & Islam, 2007) (Jin, Liu, Hsu & Kao, 2005) (Ferentinos & Tsiligiridis, 2007) (Wazed, Bari, Jaekel & Bandyopadhyay, 2007) (Rahmani, Fakhraie, & Kamarei, 2006) (Qiu, Wu, Burns, & Holzhauer, 2006). However, most of the research topics of WSNs using genetic algorithms remain few or completely unexplored.

CONCLUSION

This article discussed the application of genetic algorithms in wireless sensor networks. The basic idea of GA was discussed and some specific considerations for WSNs were made, including crossover, mutation and definition of the fitness function. The mainly performance parameters may be divided in three groups: energy, connectivity and application specific. Since WSNs have many objectives to be optimised, GA is a promising candidate to be used in WSNs design.

KEY TERMS

Cluster-Based Architecture: Sensor networks architecture where communication occurs between sensors of a cluster and a selected cluster head that collects the information obtained by the sensors in its cluster.

Cluster Head: Sensor node responsible for gathering data of a sensor cluster and transmitting them to the sink node.

Crossover: Genetic operator used to vary the programming of a chromosome or chromosomes from one generation to the next.

Energy Parameters: Parameters that affect the battery consumption of the sensors, including the energy consumed due to sensing, communication and computational tasks.

Fitness Function: A particular type of objective function that quantifies the optimality of a solution in a genetic algorithm.

Genetic Algorithms: Search technique used in computing to find true or approximate solutions to optimization and search problems.

Mutation: The occasional (low probability) alteration of a bit position.

Network Lifetime: Time until the first sensor node or group of sensor nodes in the network runs out of energy.

Sensor Node: Network node with components for sensing, data processing and communication.

Wireless Sensor Networks: A network of spatially distributed devices using sensors to monitor conditions at different locations, such as temperature, sound, pressure, etc.

Genetic Fuzzy Systems Applied to Ports and Coasts Engineering

Óscar Ibáñez

University of A Coruña, Spain

Alberte Castro

University of Santiago de Compostela, Spain

INTRODUCTION

Fuzzy Logic (FL) and fuzzy sets in a wide interpretation of FL (in terms in which fuzzy logic is coextensive with the theory of fuzzy sets, that is, classes of objects in which the transition from membership to non membership is gradual rather than abrupt) have placed modelling into a new and broader perspective by providing innovative tools to cope with complex and ill-defined systems. The area of fuzzy sets has emerged following some pioneering works of Zadeh (Zadeh, 1965 and 1973) where the first fundamentals of fuzzy systems were established.

Rule based systems have been successfully used to model human problem-solving activity and adaptive behaviour. The conventional approaches to knowledge representation are based on bivalent logic. A serious shortcoming of such approaches is their inability to come to grips with the issue of uncertainty and imprecision. As a consequence, the conventional approaches do not provide an adequate model for modes of reasoning. Unfortunately, all commonsense reasoning falls into this category.

The application of FL to rule based systems leads us to fuzzy systems. The main role of fuzzy sets is representing Knowledge about the problem or to model the interactions and relationships among the system variables. There are two essential advantages for the design of rule-based systems with fuzzy sets and logic:

- The key features of knowledge captured by fuzzy sets involve handling uncertainty.
- Inference methods become more robust and flexible with approximate reasoning methods of fuzzy logic.

Genetic Algorithms (GAs) are a stochastic optimization technique that mimics natural selection (Holland, 1975). GAs are intrinsically robust and capable of determining a near global optimal solution. The use of GAS is usually recommended for optimization in high-dimensional, multimodal complex search spaces where deterministic methods normally fail. GAs explore a population of solutions in parallel. The GA is a searching process based on the laws of natural selections and

Figure 1. A typical GA cycle

genetics. Generally, a simple GA contains three basic operations: selection, genetic operations and replacement. A typical GA cycle is shown in Fig. 1.

In this paper it is shown how a genetic algorithm can be used in order to optimize a fuzzy system which is used in wave reflection analysis at submerged breakwaters.

BACKGROUND

Many works have been done in the area of artificial intelligence applied to Coastal Engineering. It can be said that Artificial Intelligence methods have a wide acceptance among Coastal & Ports Engineers. Artificial Neural Network has been applied for years with very good results. The big drawback is their inability to explain their results, how have reached them, because they work as a black box and it can not be known what happen inside them. Over the last few years, a lot of works about fuzzy systems with engineering applications have been developed (Mercan, Yagci & Kabdasli, 2003; Dingerson, 2005; Gezer, 2004; Ross, 2004; Oliveira, Souza & Mandorino, 2006; Ergin, Williams & Micallef, 2006; Yagci, Mercan, Cigizoglu & Kabdasli, 2005). These systems have the advantage of being easy to understand (their solutions) and the capacity to handle uncertainty. However, most of these found a problem with knowledge extraction; when they try to define their RB and DB, in many cases for the difficulty of the problem and more often for the difficulty of represent all the expert knowledge in some rules and membership function.

To overcome these problems Genetic Fuzzy Systems (GFS) emerged, in which expert advice it is not as important as in Fuzzy System (FS) since it could be only needed to define the variables involved and its work domain. GFS (Cordón, et al., 2001) allow us to be less dependent on expert knowledge and in addition it is easier to reach better accuracy with these systems since they can realize a tuning process for membership functions and refine the rule set in order to optimize it. Following a specific application of GFS for wave reflection analysis at submerged breakwaters is presented.

While other kinds of techniques have been applied to that problem (Taveira, 2005; Kobayasi & Wurjanto, 1989; Abul-Azm, 1993; Losada, Silva & Losada, 1999),

it is a novel approach to estimate reflection coefficient, since a GA will determine the membership functions for each variable involved in the fuzzy system.

ANALYSIS OF WAVE REFLECTION AT SUBMERGED BREAKWATERS WITH A GENETIC FUZZY SYSTEM

Fuzzy rule-based systems can be used as a tool for modelling non-linear systems especially complex physical systems. It is well known fact that the breakwater damage ratio estimation process is dynamic and non-linear, so classical methods cannot be able to capture this behaviour resulting in unsatisfactory solutions.

The Knowledge Base (KB) is the FS component comprising the expert knowledge knows about the problem. So is the only component of the FS depending on the concrete application and it makes the accuracy of the FS depends directly on its composition. The KB is comprised of two components, a Data Base (DB), containing the definitions of fuzzy rules linguistic labels, that is, the membership functions of the fuzzy sets, and a Rule Base (RB), constituted by the collection of fuzzy rules representing the expert knowledge.

There are many tasks that have to be performed in order to design a concrete FS. As it has been shown previously, the derivation of the KB is the only one directly depending on the problem to solve. It is known that the more used method in order to perform this task is based directly on extracting the expert experience from the human process operator. The problem arises when there are not able to express their knowledge in terms of fuzzy rules. In order to avoid this drawback, researches have been investigating automatic learning methods for designing FSs by deriving automatically an appropriate KB for the FS without necessary of its human expert.

The Genetic algorithms (GA) have demonstrated to be a powerful tool for automating the definition of the KB since adaptativa control, learning and self-organization can be considered in a lot of cases as optimization or search process. The fuzzy systems making use of GA in their design process are called generically GFSs.

These advantages have extended the use of GAs in the development of a wide range of approaches for designing FSs in the last years. It is possible to

distinguish three different groups of genetic FS design process according to the KB components included in the learning process. These ones are the following:

- Genetic definition of the Fuzzy System Data Base (Bolata and Nowé, 1995; Fathi-Torbaghan and Hildebrand, 1994; Herrera and Verdegay, 1995b; Karr, 1991b).
- Genetic derivation of the Fuzzy System Rule Base (Bonarini, 1993; Karr, 1991a; Thrift, 1991).
- Genetic learning of the Fuzzy System Knowledge Base (Cooper and Vidal, 1993; Herrera, Lozano and Verdegay, 1995a; Leitch and Probert, 1994; Lee and Takagi, 1993; Ng and Lee, 1994).

In this paper, we create a Fuzzy System which predicts reflection coefficient at a different model of submerged breakwaters. To do this task, a part of this Fuzzy System, the Data Base, is defined and tuning by a Genetic Algorithm.

SUBMERGED BREAKWATER DOMAIN

Submerged breakwaters are effective shore protection structure against wave action with a reduced visual impact (see fig. 2).

To predict reflection coefficient several parameters have to be taken into account, they are:

- Rc: water level above crest.

- Hs: significant wave height.
- d: water depth.
- Tp: peak period or
- Lp: peak wavelength

These are parameters that connect the submerged breakwater model and the wave. The parameters that identified the submerged breakwater model (see fig. 3) are: the height (h) and the crest width (B), n (cotangent α), breakwater slope (α) and slope nature (smooth or rough). To predict the reflection coefficient, the first ones were used but in many cases dimensionless parameters were used instead the parameters separately.

A lot of tests were done with different number of input variables and different number of fuzzy sets for each membership function. Depending of the variables and membership function number, a set of rules were established for each case.

PHYSICAL TEST

A large number of tests have been carried out (Taveira-Pinto, 2001) with different water deeps and wave conditions for each model (figure 3 shows the general layout of the tested models). Eight impermeable physical models have been tested with different geometries (crest width, slope), different slope nature (smooth, rough), values for $\tan \alpha$ (from 0.20 to 1.00) and n (from 1 to 5) in the old unidirectional wave tank of the Hydraulics Laboratory of the Faculty of Engineering of the University of Porto.

Figure 2. Outline of a submerged breakwater and its action

Figure 3. Diagram of interesting variables taken into account in a submerged breakwater

GENETIC FUZZY SYSTEM

The target of the GA is find the better distribution for the membership functions (optimization task) inside of the domain of each variable, so that minimizes the error of the created fuzzy system when it is applied to the training set

Genome Encoding

Each individual of the GA represents the Data Base of the fuzzy system that means all the membership functions. Each gen contains the position of one point of one membership function. As can be seen in fig. 4, one variable X with all its fuzzy sets is coding as a chain of real numbers.

The used codification allows different kinds of membership functions (triangular, trapezoid, Gaussian, etc...) codifying the representative points in the chromosome so the resultant chromosome is variable size.

Genetic Operators

Genetic operators were limited in order to generate meaningful fuzzy systems.

- **Crossover:** The classical crossover operator, with one-point, n-point or uniform crossover, has to be limited in its possible cross points. To avoid

meaningless membership functions it is only allows exchange the genetic material corresponding to whole variables.

- **Mutation:** When a mutation happens, the new value of the gen will be between a lower and an upper limit, both have worked out from the neighbour points of the corresponding membership function and its neighbour membership functions.
- **Selection:** The selection method is tournament with elitism (Blickle, 1997).

Fitness

The way of find out what individual is better than other is the fitness function. In this case, one individual represent a part of a fuzzy system (DB) and with the rest of the fuzzy system (static RB) the fitness of that individual can be calculate. For that aim the physical test is split in two new sets, one was used as a training set and the other as a test set. For each physical test of the training set, the corresponding value for the input variables are introducing in the fuzzy system (individual in the genetic population). Once is calculated the output with a Mandani (Mandani, 1977) strategy and a Centroid defuzzification method, the result is compared to the output of the physical test; the difference is piled up for every tests in the training set and once all test have been introduced in the fuzzy system (one individual from the GA) and have been calculated its error, the

Figure 4. Piece of a chromosome. X_{ij} contains the position of one point (i) of one membership function (j)

addition of the errors is the fitness function value for the individual. The smaller is the total error the better is the individual.

Results

Good results were obtained (from 85% to 95% of success) for the different tests done. Tests differ from one another for the number of input variables and the number of rules as well as genetic algorithm parameters. An easy understanding test is explained following:

- Selected dimensionless parameters: R_c/H_s and d/L_p .
- Both input variables were split in two (Low and High) trapezoidal membership functions.
- The output variable Cr (reflection coefficient) was split in three (Low, Medium and High) trapezoidal membership functions.
- The rule set was made up of by three rules:
 - o If ($R_c/H_s = \text{Low}$) and ($d/L_p = \text{Low}$) then ($Cr = \text{High}$)
 - o If ($R_c/H_s = \text{Low}$) and ($d/L_p = \text{High}$) then ($Cr = \text{Medium}$)
 - o If ($R_c/H_s = \text{High}$) and ($d/L_p = \text{Low}$) then ($Cr = \text{Medium}$)

The training set was made up of 24 physical tests and the medium square error in that step was 0.84. Resultant membership functions can be seen in fig. 5. The test set was made up of 11 physical tests and the mean square error in that step was 0.89.

FUTURE TRENDS

Give the GA the capacity to optimize rules so that the system definition becomes easier and better results can be reached. The GA must be able to generate individuals with different number rules and different kind of rules at the same time that these individuals represent different membership functions.

CONCLUSION

- A Genetic Fuzzy System was development to estimate the wave reflection coefficient at submerged breakwaters.
- Good results were obtained (near to 90% accuracy) but better results (near to 97% accuracy) are difficult to understand inside the fuzzy theory.

Figure 5. Resultant membership functions from tuning process of a DB by GA

- It is a hard task to choose the rule set and furthermore the system's accuracy depends on this set a lot.
- The more inputs the problem have the more difficult become to define the rule set.

KEY TERMS

Fuzzification: Establishes a mapping from crisp input values to fuzzy set defined in the universe of discourse of that input.

Fuzzy System (FS): Any FL-based system, which either uses FL as the basis for the representation of different forms of knowledge, or to model the interactions and relationships among the system variables.

Genetic Algorithm: General-purpose search algorithms that use principles by natural population genetics to evolve solutions to problems

Genetic Fuzzy System: A fuzzy system that is augmented with an evolutionary learning process.

Mamdani Fuzzy Rule-Based System: A rule based system where fuzzy logic (FL) is used as a tool for representing different forms of knowledge about the problem at hand, as well as for modelling the interactions and relationships that exist between its variables.

Mamdani Inference System: Derives the fuzzy outputs from the inputs fuzzy sets according to the relation defined through fuzzy rules. Establishes a mapping between fuzzy sets $U = U_1 \times U_2 \times \dots \times U_n$ in the input domain of X_1, \dots, X_n and fuzzy sets V in the output domain of Y . The fuzzy inference scheme employs the generalized modus ponens, an extension to the classical modus ponens (Zadeh, 1973).

Takagi-Sugeno-Kang Fuzzy Rule-Based System: A rule based system whose antecedent is composed of linguistic variables and the consequent is represented by a function of the input variables.

Grammar–Guided Genetic Programming

INTRODUCTION

Evolutionary computation (EC) is the study of computational systems that borrow ideas from and are inspired by natural evolution and adaptation (Yao & Xu, 2006, pp. 1-18). EC covers a number of techniques based on evolutionary processes and natural selection: evolutionary strategies, genetic algorithms and genetic programming (Keedwell & Narayanan, 2005).

Evolutionary strategies are an approach for efficiently solving certain continuous problems, yielding good results for some parametric problems in real domains. Compared with genetic algorithms, evolutionary strategies run more exploratory searches and are a good option when applied to relatively unknown parametric problems.

Genetic algorithms emulate the evolutionary process that takes place in nature. Individuals compete for survival by adapting as best they can to the environmental conditions. Crossovers between individuals, mutations and deaths are all part of this process of adaptation. By substituting the natural environment for the problem to be solved, we get a computationally cheap method that is capable of dealing with any problem, provided we know how to determine individuals' fitness (Manrique, 2001).

Genetic programming is an extension of genetic algorithms (Couchet, Manrique, Ríos & Rodríguez-Patón, 2006). Its aim is to build computer programs that are not expressly designed and programmed by a human being. It can be said to be an optimization technique whose search space is composed of all possible computer programs for solving a particular problem. Genetic programming's key advantage over genetic

algorithms is that it can handle individuals (computer programs) of different lengths.

Grammar-guided genetic programming (GGGP) is an extension of traditional GP systems (Whigham, 1995, pp. 33-41). The difference lies in the fact that they employ context-free grammars (CFG) that generate all the possible solutions to a given problem as sentences, establishing this way the formal definition of the syntactic problem constraints, and use the derivation trees for each sentence to encode these solutions (Dounias, Tsakonas, Jantzen, Axer, Bjerregard & von Keyserlingk, D. 2002, pp. 494-500). The use of this type of syntactic formalisms helps to solve the so-called closure problem (Whigham, 1996). To achieve closure valid individuals (points that belong to the search space) should always be generated. As the generation of invalid individuals slows down convergence speed a great deal, solving this problem will very much improve the GP search capability. The basic operator directly affecting the closure problem is crossover: crossing two (or any) valid individuals should generate a valid offspring. Similarly, this is the operator that has the biggest impact on the process of convergence towards the optimum solution. Therefore, this article reviews the most important crossover operators employed in GP and GGGP, highlighting the weaknesses existing nowadays in this area of research. We also propose a GGGP system. This system incorporates the original idea of employing ambiguous CFG to overcome these weaknesses, thereby increasing convergence speed and reducing the likelihood of trapping in local optima. Comparative results are shown to empirically corroborate our claims.

BACKGROUND

Koza defined one of the first major crossover operators (KX) (1992). This approach randomly swaps subtrees in both parents to generate offspring. Therefore, it tends to disaggregate the so-called building blocks across the trees (that represent the individuals). The building blocks are those subtrees that improve fitness. This over-expansion has a negative effect on the fitness of the individuals. Also, this operator's excessive exploration capability leads to another weakness: an increase in the size of individuals, which affects system performance, and results in a lower convergence speed (Terrio & Heywood, 2002). This effect is known as bloat or code bloat.

There is another important drawback: many of the generated offspring are syntactically invalid as the crossovers are done completely at random. These individuals should not be part of the new population because they do not provide a valid solution. This seriously undermines the convergence process. Figure 1 shows a situation where one of the two individuals generated after Koza's crossover breaches the constraints established by a hypothetical grammar whose sentences represent arithmetic equalities.

The strong context preservative crossover operator (SCPC) avoids the problem of desegregation of building

blocks (also called context) across the trees by setting severe (strong) constraints for tree nodes considered as possible candidates for selection as crossover nodes (D'haesler, 1994, pp. 379-407). A system of coordinates is defined to univocally identify each node in a derivation tree. The position of each node within the tree is specified along the path that must be followed to reach a given node from the root. To do this, the position of a node is described by means of a tuple of n coordinates $T = (b_1, b_2, \dots, b_n)$, where n is the node's depth in the tree, and b_i indicates which branch is selected at depth i (counting from left to right). Figure 2 shows an example representing this system of coordinates.

Only nodes with the same coordinates from both parents can be swapped. For this reason, a subtree may possibly never migrate to another place in the tree. This limitation can cause serious search space exploration problems, as the whole search space cannot be covered unless each function and terminal appears at every possible coordinate at least once in any one individual in the population. This failure to migrate building blocks causes them to evolve separately in each region, causing a too big an exploitation capability, thereby increasing the likelihood of trapping in local optima (Barrios, Carrascal, Manrique & Ríos, 2003, pp. 275-293).

As time moves on, the code bloat phenomenon becomes a serious problem and takes an ever more prominent role. To avoid this, Crawford-Marks &

Figure 1. Incorrect operation of Koza's crossover operator

Figure 2. The system of coordinates defined in SPCP

Spector (2002) developed the Fair crossover (pp. 733-739). This is a modified version of the approach proposed by Langdon (1999, pp. 1092-1097). Tree size is controlled as follows. First, a crossover node in the first parent is selected at random and the length, l , of the subtree extending from the node to the leaves is calculated. Then, a node is also selected at random in the second parent, and the length, l_2 , for this second subtree is calculated. If l_2 is within the range $[l - l/4, l + l/4]$, then the crossover node for the second parent is accepted, and the two subtrees are swapped. If not, another crossover node is selected at random for the second parent and the check is run again. This way, the size of the subtree in the second parent to be swapped is controlled and limited, so the code bloat phenomenon is avoided. Another aspect to comment here is that the range in which l_2 must be included can be modified to afford specific problems more efficiently, but the range originally proposed works fine for most of them.

Whigham proposed one of the most commonly used operators (WX) in GGGP (1995, pp. 33-41). Because of its sound performance in such systems, it has become the de facto standard and is still in use today (Rodrigues & Pozo, 2002, pp. 324-333), (Hussain, 2003), (Grosman & Lewin, 2004, pp. 2779-2790). The algorithm works as follows. First, as all the terminal symbols have at least one non-terminal symbol above them, then, without loss of generality, the crossover nodes can be confined exclusively to locations on nodes containing non-terminal symbols. A non-terminal node belonging to the first parent is selected at random. Then a non-terminal node labeled with the same non-terminal symbol as in the first-chosen crossover node is selected from the second parent. This assures that generated individuals belong

to the grammar-generated language, as the crossed nodes share the same symbol. This operator's main flaw is that there are other possible choices of node in the second parent that are not explored and that could end in the target solution (Manrique, Marquez, Ríos & Rodríguez-Patón, 2005, pp. 252-261).

THE PROPOSED CROSSOVER OPERATOR FOR GGGP SYSTEMS

The proposed operator is a general-purpose operator designed to work in any GGGP system. It takes advantage of the key feature that defines a CFG as ambiguous: the same sentence can be obtained by several derivation trees. This implies that there are several individuals representing the solution to a problem. It is therefore easier to find. This operator consists of eight steps:

1. Choose a node, except the axiom, with a non-terminal symbol randomly from the first parent. This node is called crossover node and is denoted CN1.
2. Choose the parent of CN1. As we are working with a CFG, this will be a non-terminal symbol. The right-hand sides of all its production rules are stored in the array R.
3. The derivation produced by the parent of CN1 is called main derivation, and is denoted $A ::= C$. Calculate the derivation length l as the number of symbols in the right-hand side of the main derivation. Having l , the position (p) of CN1 in the main derivation and C, define the three-tuple $T(l, p, C)$.
4. Delete from R all the right-hand sides with different lengths from the main derivation.
5. Remove from R all those right-hand sides in which there exists any difference between the symbols (except the one located in position p) in each right-hand side and the symbols in C.
6. The set X is formed by all the symbols in the right-hand sides of R that are in position p. X contains all the non-terminal symbols of the second parent that can be chosen as a crossover node (CN2).
7. Choose CN2 randomly from X, discarding all the nodes that will generate offspring trees with a size greater than a previously established value D.

8. Calculate the two new derivation trees produced as offspring by swapping the two subtrees whose roots are CN1 and CN2.

The underlying idea of this algorithm consists on calculating which are the non-terminal symbols that can substitute the symbol contained in CN1, bearing in mind that the production rule that contains CN1 keeps being valid. Since all non-terminal symbols that can generate valid production rules are taken into account in the crossover process, this operator takes advantage of ambiguous grammars.

The proposed crossover operator has primarily three attractive features: a) step 7 states a code bloat control mechanism, b) the offspring produced are always composed of two valid trees and c) step 6 indicates that all the possible nodes of the second parent that can generate valid individuals are taken into account, not only those nodes with the same non-terminal symbol as the one chosen for the first parent. This third feature increases the GGGP system's exploration capability, which avoids trapping in local optima and takes advantage of there being more than one derivation tree (potential solution to the problem) for a single sentence.

Results

We present and discuss the results achieved by the crossover operators described in the background section and the operator that we propose. To do so, we have tackled a complex classification problem: the real-world task of providing breast cancer prognosis (benign or malignant) from the morphological characteristics of microcalcifications. Microcalcifications are small mineral deposits in breast tissue that could constitute cancer. This experiment involved searching a knowledge base of fuzzy rules that could give such a prognosis.

The data employed for giving a disease prognosis are: patient's age, lesion size, lesion location in the breast, and particular features of the microcalcifications: number, distribution and type. Number indicates the quantity of existing clustered microcalcifications, distribution shows how they are clustered and type reflects the individual morphology of the microcalcifications. To run the tests, 365 microcalcifications were selected at random. Of these, 315 lesions were randomly selected for use as genetic programming system training cases with the different crossover operators described. After training, the fittest individual was selected to form a knowledge base with the fuzzy rules encoded by this individual. Then, the knowledge base was tested with

Figure 3. Average convergence speed for each crossover operator

the 50 remaining lesions not chosen during the training phase to output the number of correctly classified patterns in what we have called the testing phase.

The CFG employed was formed by 19 non-terminal symbols, 54 terminals and 51 production rules, some of them included to obtain an ambiguous grammar. The population size employed was 1000, the upper bound for the size of the derivation trees was set to 20. The fitness function consisted of calculating the number of well-classified patterns. Therefore, the greater the fitness, the fitter the individual is, with the maximum limit of 315 in the training phase and 50 in the test.

Figure 3 shows the average evolution process for each of the five crossover operators in the training phase after 100 executions.

It is clear from Figure 3 that KX yields the worst results, because it maintains an over-diverse population and allows invalid individuals to be generated. This prevents it from focusing on one possible solution. The effect of Fair is just the opposite, leading very quickly to one of the optimal solutions (this is why it has a relatively high convergence speed initially), and

slowing down if convergence is towards a local optimum (which happens in most cases). WX and SCPC produce good results, bettered only by the proposed crossover. Its high convergence speed evidences the benefits of taking into account all possible nodes of the second parent that can generate valid offspring.

Table 1 shows examples of fuzzy rules output in one of the executions for the best two crossover operators—WX and the proposed operator—once the training phase was complete.

Table 2 shows the average number (rounded up or down to the nearest integer) of correctly classified patterns after 100 executions, achieved by the best individual in the training and test phases, and the percentage of times that the system converged prematurely.

KX again yields the worst results, correctly classifying just 57.46% (181/315) of patterns in the training phase and 54% (27/50) in the testing phase. SCPC and Fair crossovers also return insufficient results: around 59% in the training phase and 54%-56% in the testing phase, although, as shown in Figure 3, SCPC has a higher convergence speed. Finally, note the similarity

Table 1. Some knowledge base fuzzy rules output by two GGGP systems

| Crossover operator | Rule 1 | Rule 2 |
|--------------------|--|---|
| WX | IF NOT (type=branched) OR (number=few) THEN (prognosis=benign) | |
| Proposed | IF NOT (age=middle) AND NOT (location=subaerolar) AND NOT(type=oval) THEN (prognosis=malignant) | IF (type=heterogeneous) THEN (prognosis=malignant) |

Table 2. Average number of correctly classified patterns and unsuccessful runs

| Crossover operator | Training | Testing | Unsuccessful runs |
|--------------------|------------------|-------------|-------------------|
| KX | 181/315 (57.46%) | 27/50 (54%) | 36% |
| SCPC | 186/315 (59.04%) | 28/50 (56%) | 14% |
| Fair | 185/315 (58.73%) | 27/50 (54%) | 15% |
| WX | 191/315(60.63%) | 30/50 (60%) | 8% |
| Proposed | 191/315(60.63%) | 31/50 (62%) | 2% |

between WX and the proposed operator. However, the proposed operator has higher speed of convergence and is less likely to get trapped in local optima, as it converged prematurely only twice in 100 executions.

FUTURE TRENDS

The continuation of the work described in this article can be divided into two main lines of investigation in GGGP. The first involves finding an algorithm that can estimate the maximum sizes of the trees generated throughout the evolution process to assure that the optimal solution will be reached. This would overcome the proposed crossover operator's weakness of not being able to reach a solution because the permitted maximum tree size is too restrictive for it to be able to reach a good solution, whereas this solution could be found if individuals were just a little larger.

The second interesting line of research derived from this work is the use of ambiguous grammars. It has been empirically observed that using the proposed operator combined with ambiguous grammars in GGGP systems benefits convergence speed. However, "too much ambiguity" is damaging. The idea is to get an ambiguity measure that can answer the question of how much ambiguity is needed to get the best results in terms of efficiency.

CONCLUSION

This article summarizes the latest and most important advances in GGGP, paying special attention to the crossover operator, which (alongside the initialization method, the codification of individuals and, to a lesser extent, the mutation operator, of course) is chiefly responsible for the convergence speed and the success of the evolution process.

GGGP systems are able to find solutions to any problem that can be syntactically expressed by a CFG. The proposed crossover operator provides GGGP systems with a satisfactory balance between exploration and exploitation capabilities. This results in a high convergence speed, while eluding local optima as the reported results demonstrate. To be able to achieve such good results, the proposed crossover operator includes a computationally cheap mechanism to control bloat, it always generates syntactically valid offspring and it

can choose any node from the second parent to generate the offspring, rather than just those nodes with the same non-terminal symbols as the one chosen in the first parent.

KEY TERMS

Ambiguous Grammar: Any grammar in which different derivation trees can generate the same sentence.

Closure Problem: Phenomenon that involves always generating syntactically valid individuals.

Code Bloat: Phenomenon to be avoided in a genetic programming system convergence process involving the uncontrolled growth, in terms of size and complexity, of individuals in the population

Convergence: Process by means of which an algorithm (in this case an evolutionary system) gradually approaches a solution. A genetic programming system is said to have converged when most of the individuals in the population are equal or when the system cannot evolve any further.

Fitness: Measure associated with individuals in an evolutionary algorithm population to determine how good the solution they represent is for the problem.

Genetic Programming: A variant of genetic algorithms that uses simulated evolution to discover functional programs to solve a task.

Grammar-Guided Genetic Programming: The application of analytical methods and tools to data for the purpose of identifying patterns, relationships or obtaining systems that perform useful tasks such as classification, prediction, estimation, or affinity grouping.

Intron: Segment of code within an individual (subtree) that does not modify the fitness, but is on the side of convergence process.

Granular Computing

Georg Peters

Munich University of Applied Sciences, Germany

INTRODUCTION

It is well accepted that in many real life situations information is not certain and precise but rather uncertain or imprecise. To describe uncertainty probability theory emerged in the 17th and 18th century. Bernoulli, Laplace and Pascal are considered to be the fathers of probability theory. Today probability can still be considered as the prevalent theory to describe uncertainty.

However, in the year 1965 Zadeh seemed to have challenged probability theory by introducing fuzzy sets as a theory dealing with uncertainty (Zadeh, 1965). Since then it has been discussed whether probability and fuzzy set theory are complementary or rather competitive (Zadeh, 1995). Sometimes fuzzy sets theory is even considered as a subset of probability theory and therefore dispensable. Although the discussion on the relationship of probability and fuzziness seems to have lost the intensity of its early years it is still continuing today. However, fuzzy set theory has established itself as a central approach to tackle uncertainty. For a discussion on the relationship of probability and fuzziness the reader is referred to e.g. Dubois, Prade (1993), Ross et al. (2002) or Zadeh (1995).

In the meantime further ideas how to deal with uncertainty have been suggested. For example, Pawlak introduced rough sets in the beginning of the eighties of the last century (Pawlak, 1982), a theory that has risen increasing attentions in the last years. For a comparison of probability, fuzzy sets and rough sets the reader is referred to Lin (2002).

Presently research is conducted to develop a Generalized Theory of Uncertainty (GTU) as a framework for any kind of uncertainty whether it is based on probability, fuzziness besides others (Zadeh, 2005). Cornerstones in this theory are the concepts of information granularity (Zadeh, 1979) and generalized constraints (Zadeh, 1986).

In this context the term Granular Computing was first suggested by Lin (1998a, 1998b), however it still lacks of a unique and well accepted definition. So, for example, Zadeh (2006a) colorfully calls granular

computing “ballpark computing” or more precisely “a mode of computation in which the objects of computation are generalized constraints”.

BACKGROUND

Humans often speak and think in words rather than in numbers. For example, in summer we say that it is *hot* outside rather than that it is 35.32° Celsius. This means that we often define our information as an imprecise *perception-based linguistic variable* rather than as a precise *measure-based number*. The impreciseness in our formulation basically has four reasons (Zadeh, 2005):

1. *Bounded ability of human sensors and computational limits of the brain.* (1) Our human sensors do not have the abilities of a laser based speed controller. So we cannot quantify the speed of a racing car as 252.18 km/h in Albert Park, Melbourne. However on the linguistic level we can define the car as *fast*. (2) Most people cannot numerically calculate the exact race distance given by $5,303 \text{ km} * 53 \text{ turns} = 307.574 \text{ km}$ due to computational limits of their brains. However they probably estimate that it will be *around 300 km*.
2. *Lack of numerical information.* Melbourne is considered as a shopping paradise in Australia since there are *countless* shops. Maybe only local government knows the exact number of shops.
3. *Qualitative, non quantifiable information.* Much information is provided rather qualitative than quantitative. If one describes the quality of a pizza in an Italian restaurant in Lygon Street in Melbourne's suburb Carlton only a qualitative, linguistic judgment like *excellent* or *very good* is possible. The judgment is hardly to be quantifiable (beside a technical counting of the olives or the weight of the salami etc.).

4. *Tolerance for imprecision.* Recall the example, Melbourne as a shopping paradise, given above. To define Melbourne as shopping paradise its exact number of shops is not needed. It is sufficient to know that there are many shops. This tolerance for impression often makes a statement more robust and efficient in comparison to exact numerical values.

So obviously humans often prefer not to deal with precise but favor vague information that is immanent in natural language.

Humans would rarely formulate a sentence like:

With a probability of 97.34% I will see Ken, who has a height of 1.97m, at 12:05pm.

Instead most humans would prefer to say:

Around noon I will almost certainly meet tall Ken.

While the first formulation is computer compatible since it contains numbers (singletons) the second formulation seems too be to imprecise to be used as input for computers.

A central objective of the concept of granular computing is to bridge this gap and compute with words (Zadeh, 1996). This leads to the ideas of information granularity or granular computing which was introduced by Zadeh (1986, 1979).

The concept of information granularity has its roots in fuzzy set theory (Zadeh, 1965, 1997). Zadeh (1986) advanced and generalized this idea so that granular computing subsumes any kind of uncertainty and imprecision like “set theory and interval analysis, fuzzy sets, rough sets, shadowed sets, probabilistic sets and probability [...], high level granular constructs” (Bargiela, Pedrycz, 2002, p. 5). The term granular computing was first suggested by Lin (1998a, 1998b).

FUNDAMENTALS OF GRANULAR COMPUTING

Singular and Granular Values

To more formally describe the difference between natural language and precise information let us recall the example sentences given in Section 2. The infor-

Figure 1. Mapping of Singletons and granular values

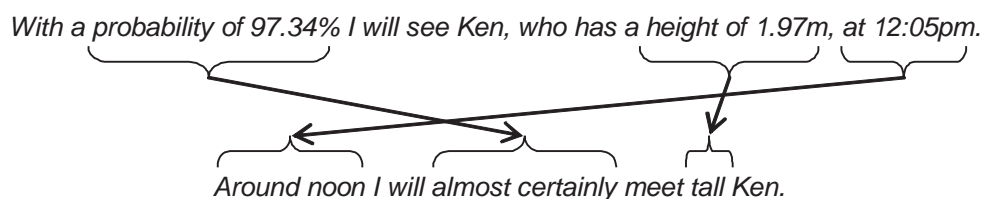

Table 1. Singular and granular values

| Variable | Singular Values | Granular Values |
|-------------|-----------------|------------------|
| Probability | 97.34% | almost certainly |
| Height | 1.97m | tall |
| Time | 12:05pm | around noon |

mation given in the two sentences can be mapped as depicted in Figure 1.

While the first sentence contains exact figures (singletons) the second sentence describes the same context using linguistic variables (granular values). A comparison of the singular and granular values is given in Table 1.

For example, the variable height can be mapped to the singleton $1.97m$ or the granule *tall*. The granule *tall* covers not only the singleton $1.97m$ but also neighbor-

hood values. See Figure 2 for an interval granulation of the singleton of the variable height; a fuzzy membership function (linguistic variable) would be another possibility for a granule of *tall* (see Figure 3).

The main difference in the representation of the variable heights is entailed by a different formulation of the constraints. While the formulation as a singleton is of bivalence nature ($\text{height}=1.97m$) a fuzzy formulation would contain memberships. This leads to the concept of generalized constraints.

Figure 2. Presentation of variable height as Singleton and granule

Figure 3. Fuzzy memberships

Generalized Constraints

Overview of Constraints

The generalization of constraints is a central concept in granular computing. The main purpose is to make classic constraints like \in (member), $=$ (equal); $<$ (smaller) and $>$ (greater) more flexible and therefore closer to the way humans think. In the following subsections we will discuss standard, primary and general constraints in more detail.

Basic Concept of Generalized Constraints

Standard Constraints. A *standard constraint* C is characterized by its bivalency (possibilistic or veristic) or probabilistic nature. Bivalent and probabilistic constraints do not have memberships degrees which indicate the degree of satisfaction of the constraint A : a variable X does or does not fulfill the standard constraint. Examples for bivalent constraints are: \in (member), $=$ (equal); $<$ (smaller) and $>$ (greater) besides others.

Primary Constraints. Zadeh (2006a) suggested the following *primary constraints*:

- Possibilistic ($r=\text{blank}$)
- Probabilistic ($r=p$)
- Veristic ($r=v$)

since they formulate the basic perceptions possibility, likelihood and truth. In contrast to the standard constraints bivalency is no longer required for the possibilistic and veristic constraints. Therefore standard constraints are included in the primary constraints.

Applying the primary constraints to our example the second “Ken sentence” of Section 2 we get:

- Possibilistic Constraint ($X \text{ is } R$): *Ken is tall* \rightarrow *Height(Ken) is tall* (see Dubois, Prade (1998) for semantics of fuzzy sets including possibility (Zadeh, 1978)).
- Probabilistic Constraint ($X \text{ isp } R$): *Actual arrival time (X) at meeting point* $\rightarrow X \text{ isp } N(\mu, \sigma^2)$ is e.g. normal distributed around the agreed meeting time μ .
- Veristic Constraint ($X \text{ isv } R$): *Ken is at the meeting point at 12:05pm* \rightarrow *Present(Ken, meeting point) isv 12:05pm*.

Generalized Constraints. Further constraints include (Zadeh, 2005) usuality ($r=u$), random set ($r=rs$), fuzzy graph ($r=fg$), bimodal ($r=bm$) and group ($r=g$). The set of general constraints consists of these and the primary constraints. So, formally a generalized constraints (GC) is given by (Zadeh, 2005):

$$GC(X): X \text{ isr } R$$

with X the constrained variable and R the non-bivalent relation. In the term *isr* the letter r defines the semantics or the modality of the constraint as describe above.

Generalized Constraint Language

To formally describe generalized constraints Zadeh (2006b) suggests a Generalized Constraint Language (GCL). In Section 3.2.2 we already used the GCL in the presented example, e.g. the mapping: *Ken is tall* \rightarrow *Height(Ken) is tall*, which has the form

$$p \rightarrow X \text{ isr } R$$

with p an expression in natural language. In this context Zadeh (2006b) defines the translation of natural language into GCL as *precisation*. The precisation can lead to *v-precise* and/or *m-precise* results:

- *v-precisation*: a precise value is obtained. *v-precisation* has *s-precisation* (singleton), *cg-precisation* (crisp granular) and *g-precisation* (granular) as its modalities. *s-precisation* leads to a singleton, while *cg-precisation* leads to an crisp interval. *g-precisation* is the most general form of precisation and leads to fuzzy intervals, fuzzy graphs besides others.
- *m-precisation*: a precise meaning is obtained. *m-precisation* can further divided into the modalities *mm-precisation* (machine-oriented) and *mh-precisation* (human-oriented).

Examples: (1) *Ken is between a and b meters tall* is *m-precise* and since the variables a and b are not specified *v-imprecise*. (2) *Ken is approximately c meters tall* \rightarrow *Ken is a meters tall* is a *s-precisation*. The term *approximately c* can also be abbreviated as c^* . The star indicates that c is a granular value.

Figure 4. Rough sets

In contrast to precision granulation leads to an imprecision of the information. Obviously the translation *Ken is 1.97m* \rightarrow *Ken is c meters tall* is a v-impresiation and *Ken is c meters tall* \rightarrow *Ken is tall* a m-impresiation.

So for example, rough sets can be interpreted as cascading cg-impresiation. In rough set theory (Pawlak, 1982) a set is described by a lower and upper approximation ($\downarrow A$ and $\uparrow A$ respectively). The lower approximation is a subset of the upper approximation. While the objects in the lower approximation surely belong to the corresponding set the objects in a upper approximation might belong to the set.

Therefore rough set theory provides an example of a cascading granulation: $X \uparrow \downarrow A \uparrow \uparrow A$ (see Figure 4).

Deduction Rules

Principal Deduction Rules

In this Section we regard the term granular computing in its literally meaning: how to compute with granules and focus on principal deductions (Zadeh, 2005, 2006b):

- Conjunction
- Projection
- Protagation

For more details on deduction rules the reader is referred to Zadeh (2005, 2006b).

Generalized Extension Principle

One of the most fundamental theorem in fuzzy logic is the Extension Principle (Zadeh, 1975, Zimmermann, 2001). Basically the Extension Principle defines how the memberships $\mu_y(y)$ of an endogenous variable

$$Y=f(X)$$

can be determined with X and Y singletons and $\mu_x(X)$ given. A simple transformation $\mu_y(Y)=\mu_y(f(X))=\mu_x(X)$ does not generally provide a unique solution. Therefore, to obtain a unique solution, $\sup \mu_y(f(X))$ is taken.

The Generalized Extension Principle (Zadeh, 2006a) establishes a relationship between

$$Y^*=f^*(X^*)$$

$$Gr(Y) \text{ is } Gr(X)$$

with Y^* , X^* and $f^*(\cdot)$ granules. It can be considered as primary deduction rule since many others deduction rules can be derived from it (Zadeh, 2006b).

Example

Let us consider an example (Zadeh, 2005, 2006a, 2006b):

The following linguistic statement is given:

Most Swedes are tall \rightarrow (*Height(Swedes) are tall*) is *most*.

First let us specify

$$\text{Swedes are tall} \rightarrow \int X(h)\mu_{tall}(h)dh$$

with $X(h)$ the height density function and $\mu_{tall}(h)$ the membership function for the linguistic variable *tall*.

Second we have to apply the linguistic variable *most* to the expression *Swedes are tall* and obtain:

$$\text{Most (Swedes are tall)} \rightarrow \mu_{most}(\int X(h)\mu_{tall}(h)dh)$$

As result we get a precise formulation of the given linguistic statement.

CONCLUSION AND FUTURE RESEARCH

Granular Computing is a mighty framework to deal with uncertainty. Information granules can include probabilistic as well as possibilistic phenomena besides others. Therefore granular computing functions as a umbrella for them without competing with them. One core advantage is that it helps to bridge the gap between (imprecise) natural language and the precision that is immanent in computers etc. Presently Zadeh is promoting his idea towards a Generalized Theory of Uncertainty in many publications and presentations. In future the Generalized Theory of Uncertainty will probably be the dominant label for anything related to this topic. Since the Generalized Theory of Uncertainty is a young but rapidly emerging new branch in science future research will go in the direction of the generalization of uncertainty concepts, e.g. from probabilistic and fuzzy clustering towards granular clustering.

KEY TERMS

Fuzzy Set Theory: Fuzzy set theory was introduced by Zahed in 1965. The central idea of fuzzy set theory is that an object belongs to more than one sets simultaneously. the closeness of the object to a set is indicated by membership degrees.

Generalized Theory of Uncertainty (GTU): GTU is a framework that shall subsume any kind of uncertainty (Zadeh 2006a). The core idea is to formulate generalized constraints (like possibilistic, probabilistic, veristic etc.). The objective of GTU is not to replace existing theories like probability or fuzzy sets but to provide an umbrella that allows to formulate any kind of uncertainty in a unique way.

Granular Computing: The idea of granular computing goes back to Zadeh (1979). The basic idea of granular computing is that an object is describe by a bunch of values in possible dimensions like indistinguishability, similarity and proximity. If a granular is labeled by a linguistic expressing it is called a linguistic variable. Zahed (2006a) defines granular computing as “a mode of computation in which the objects of computation are generalized constraints”.

Hybridization: Combination of methods like probabilistic, fuzzy, rough concepts, or neural nets, e.g. fuzzy-rough, rough-fuzzy or probabilistic-rough, or fuzzy-neural approaches.

Linguistic Variable: A linguistic variable is a linguistic expression (one or more words) labeling an information granular. For example a membership function is labeled by the expressions like “hot temperature” or “rich customer”.

Membership Function: A membership function shows the membership degrees of a variable to a certain set. For example, a temperature $t=30^{\circ}\text{C}$ belongs to the set “hot temperature” with a membership degree $\lambda_{\text{HT}}(30^{\circ})=0.8$. The membership functions are not objective but context and subject-dependent.

Rough Set Theory: Rough set theory was introduced by Pawlak in 1982. The central idea of rough sets is that some objects distinguishable while others are indiscernible from each other.

Soft Computing: In contrast to “hard computing” soft computing is collection of methods (fuzzy sets, rough sets neutral nets etc.) for dealing with ambiguous situations like imprecision, uncertainty, e.g. human expressions like “high profit at reasonable risks”. The objective of applying soft computing is to obtain robust solutions at reasonable costs.

Growing Self-Organizing Maps for Data Analysis

INTRODUCTION

Currently, there exist many research areas that produce large multivariable datasets that are difficult to visualize in order to extract useful information. Kohonen self-organizing maps have been used successfully in the visualization and analysis of multidimensional data. In this work, a projection technique that compresses multidimensional datasets into two dimensional space using growing self-organizing maps is described. With this embedding scheme, traditional Kohonen visualization methods have been implemented using growing cell structures networks. New graphical map displays have been compared with Kohonen graphs using two groups of simulated data and one group of real multidimensional data selected from a satellite scene.

BACKGROUND

Data mining first stage usually consist of building simplified global overviews of data sets, generally in graphical form (Tukey, 1977). At present, the huge amount of information and its multidimensional nature complicates the possibility to employ direct graphic representation techniques. Self-Organizing Maps (Kohonen, 1982) fit well in the exploratory data analysis since its principal purpose is the visualization and the analysis of nonlinear relations between multidimensional data (Rossi, 2006). In this sense, a great variety of Kohonen's SOM visualization techniques (Kohonen, 2001)(Utsch & Siemon, 1990)(Kraaijveld,

Mao & Jain, 1995) (Merlk & Rauber, 1997) (Rubio & Giménez 2003) (Vesanto, 1999), and some automatic map analysis (Franzmeier, Witkowski & Rückert 2005) have been proposed.

In Kohonen's SOM the network structure has to be specified in advance and remains static during the training process. The choice of an inappropriate network structure can degrade the performance of the network. Some growing self-organizing maps have been implemented to avoid this disadvantage. In (Fritzke, 1994), Fritzke proposed the Growing Cell Structures (GCS) model, with a fixed dimensionality associated to the output map. In (Fritzke, 1995), the Growing Neural Gas is exposed, a new SOM model that learns topology relations. Even though the GNG networks get best grade of topology preservation than GCS networks, due to the multidimensional nature of the output map it cannot be used to generate graphical map displays in the plane. However, using the GCS model it is possible to create networks with a fixed dimensionality lower or equal than 3 that can be projected in a plane (Fritzke, 1994). GCS model, without removal of cells, has been used to compress biomedical multidimensional data sets to be displayed as two-dimensional colour images (Walker, Cross & Harrison, 1999).

GROWING CELL STRUCTURES VISUALIZATION

This work studies the GCS networks to obtain an embedding method to project the bi-dimensional output

map, with the aim of generating several graphic map displays for the exploratory data analysis during and after the self-organization process.

Growing Cell Structures

The visualization methods presented in this work are based on self-organizing map architecture and learning process of Fritzke's Growing Cell Structures (GCS) network (Fritzke, 1994). GCS network architecture consists of connected units forming k -dimensional hypertetrahedron structures linked between them. The interconnection scheme defines the neighbourhood relationships. During the learning process, new units are added and superfluous ones are removed, but these modifications are performed in such way that the original architecture structure is maintained.

The training algorithm is an iterative process that performs a non-linear projection of the input data over the output map, trying to preserve the topology of the original data distribution. The self-organization process of the GCS networks is similar that in Kohonen's model. For each input signal the best matching unit (*bm**u*) is determined, and *bm**u* and its direct neighbour's synaptic vectors are modified. In GCS networks each neuron has associated a resource, which can represent the number of input signals received by the neuron, or the summed quantization error caused by the neuron. In every adaptation step the resource of the *bm**u* is conveniently modified. A new neuron is inserted between the unit with highest resource, q , and its direct neighbour with the most different reference vector, f , after a fixed number of adaptation steps. The new unit synaptic vector is interpolated from the synaptic vectors of q and f , and the resources values of q and f are redistributed too. In addition, neighbouring connections are modified in order to ensure the output architecture structure. Once all the training vectors have been processed a fixed number of times (epoch), the neurons whose reference vectors fall into regions with a very low probability density are removed. To guarantee the architecture structure some neighbouring connections are modified too. Relative normalized probability density estimation value proposed in (Delgado, 2004) has been used in this work to determine the units to be removed. This value provides better interpretation of some training parameters, improving the removal of cells and the topology preserving of the network.

Several separated meshes could appear in the output map when superfluous units are removed.

When the growing self-organization process finishes, the synaptic vectors of the output units along with the neighbouring connections can be used to analyze different input space properties visually.

Network Visualization: Constructing the Topographic Map

The ability to project high-dimensional input data onto a low-dimensional grid is an important property of Kohonen feature maps. By drawing the output map over a plane it will be possible to visualize complex data and discover properties or relations of the input vector space not expected in advance. Output layer of Kohonen feature maps can be printed on a plane easily, painting a rectangular grid, where each cell represents an output neuron and neighbour cells correspond to neighbour output units.

GCS networks have less regular output unit connections than Kohonen ones. When $k=2$ architecture factor is used, the GCS output layer is organized in groups of interconnected triangles. In spite of bi-dimensional nature of these meshes, it is not obvious how to embed this structure into the plane in order to visualize it. In (Fritzke, 1994), Fritzke proposed a physical model to construct the bi-dimensional embedding during the self-organization process of the GCS network. Each output neuron is modelled by a disc, with diameter d , made of elastic material. Two discs with distance d between centres touch each other, and two discs with distance smaller than d repeal each other. Each neighbourhood connection is modelled as an elastic string. Two discs connected but not touching are pulled each other. Finally, all discs are positively charged and repeal each other. Using this model, the bi-dimensional topographic coordinates of each output neuron can be obtained, and thus, the bi-dimensional output meshes can be printed on a plane.

In order to obtain the output units bi-dimensional coordinates of the topographic map (for $k=2$), a slightly modified version of this physical model has been used in this contribution. At the beginning of the training process, the initial three output neurons are placed in the plane in a triangle form. Each time a new neuron is inserted, its position in the plane is located exactly halfway of the position of the two neighbouring neurons between which it has been inserted. After this, attraction

and repulsion forces are calculated for every output neuron and its positions are consequently moved. The attraction force of a unit is calculated as the sum of individual attraction forces that all neighbouring connections exercise over it. Attraction force between two neighbouring neurons i and j , with p_i and p_j coordinates in the plane, and Euclidean distance e , is calculated as $(e-d)/2$ if $e \geq d$, and 0 otherwise. The repelling force of a unit is calculated as the sum of individual repulsion forces that all no-neighbouring output neurons exercise over it. Repelling force between two no-neighbouring neurons i and j is calculated as $d/5$ if $2d < e \leq 3d$, $d/2$ if $d < e \leq 2d$, d if $0 < e \leq d$, and 0 otherwise. There exist three basic differences between the embedding model used in this work and the Fritzke's one. First, repelling force is only calculated with no-neighbouring units. Second, attracting force between two neurons i and j is multiplied by the distance normalization $((p_j - p_i)/e)$ and by the attraction factor 0.1 (instead of 1). Last, repelling force between two neurons i and j is multiplied by the distance normalization $((p_i - p_j)/e)$ and by the repulsion factor 0.05 (instead of 0.2).

The result of applying this projection method is showed in Fig. 1. When removal of cells is performed,

different meshes are showed unconnectedly. Without any other additional information, this projection method makes possible cluster detection.

Visualization Methods

Using the projection method exposed, traditional Kohonen visualization methods can be implemented using GCS networks with $k=2$. Each output neuron is painted as a circle in a colour determined by a major parameter. When greyscale is used, normally dark and clear tones are associated with high and low values respectively. The grey scales are relative to the maximum and minimum values taken by the parameter. The nature of the data used to calculate the parameter determines three general types of methods for performing visual analysis of self-organizing maps: distances between synaptic vectors, training patterns projection over the neurons, and individual information about synaptic vectors.

All the experiments have been performed using two groups of simulated data and one group of real multidimensional data (Fig. 2) selected from a scene registered by the ETM+ sensor (Landsat 7). The input signals are defined by the six ETM+ spectral bands with

Figure 1. Output mesh projection during different self-organization process stages of a GCS network trained with bi-dimensional vectors distributed on eleven separate regions.

Figure 2. (a) Eleven separate regions in the bi-dimensional plane. (b) Two three dimensional chain-link. (c) Projection of multidimensional data of satellite image.

the same spatial resolution: TM1 to TM5, and TM7. The input data set has a total number of 1800 pixels, 1500 carefully chosen from the original scene and 300 randomly selected. The input vectors are associated to six land cover categories.

Displaying Distances

The adaptation process of GCS networks places the synaptic vectors in regions with high probability density, removing units positioned into regions with a very low probability density. A graphical representation of distances between the synaptic vectors will be a useful tool to detect clusters over the input space. Distance map, unified distance map (U-map), and distance addition map have been implemented to represent distance map information with GCS networks.

In distance map, the mean distance between the synaptic vector of each neuron and the synaptic vectors of all its direct neighbours is calculated. U-map represents the same information than distance map but, in addition it includes the distance between all the neighbouring neurons (painted in a circle form between each pair of neighbour units). Finally, the sum of the distance between the synaptic vector of a neuron and the synaptic vectors of the rest of units is calculated, when distance addition map is generated. In distance map and U-map, dark zones represent clusters and clear zones boundaries along with them. In distance addition map, neurons with near synaptic vectors appear with similar colour, and boundaries can be detected analyzing the regions where a considerable colour

variation exists. Using GCS networks, separated meshes represent different input clusters, usually. Fig. 3 shows an example of these three graphs, compared with the traditional Kohonen's maps, when an eleven separate regions distribution data set is used. GCS network represents eleven clusters in the three graphs, clearly. Distance map and U-map in Kohonen's network show the eleven clusters too, but in distance addition map it is not possible to distinguish them.

Displaying Projections

This technique takes into account the input distribution patterns to generate different values to assign to each neuron. For GCS networks, data histograms and quantization error maps have been implemented.

Generating the histogram, the number of training patterns associated to each neuron is obtained. However, when quantization error graph has to be produced, the sum of the distances between the synaptic vector of a neuron and the input vectors that lies in its *Voronoi* region is calculated. In both graphs, dark and clear zones correspond with high and low probability density areas, respectively, so it can be used in cluster analysis. Fig. 4 shows an example of these two methods compared with those obtained using Kohonen's model when chain-link distribution data set is used. Using Kohonen's model is difficult to distinguish the number of clusters present in the input space. On the other hand, GCS model has generated three output meshes, two of them representing one ring.

Figure 3. From left to right: distance map, U-map (unified distance map), and distance addition map when an eleven separate regions distribution data set is used. (a) Kohonen feature map with 10x10 grid of neurons. (b) GCS network with 100 output neurons. The right column shows the input data and the network projection using the two component values of the synaptic vectors.

Displaying Components

The displaying components technique analyzes each synaptic vector or reference vector component in an individual manner. This kind of graphs offers a visual analysis of the topology preserving of the network, and a possible detection of correlations and dependences between training data components. Direct visualization of synaptic vectors and component planes graphs have been implemented for GCS networks.

Direct visualization map represents each neuron in a circle form within its synaptic vector inside in a graphical manner. This graph can be complemented with anyone of described in the previous sections, enriching

its interpretation. A component plane map visualizes an individual component of all the synaptic vectors.

When all the component planes are generated, relations between weights can be appreciated if similar structures appear in identical places of two different component planes. Fig. 5 shows an example of these two displaying methods when multi-band data of satellite image is used. The direct visualization map shows the similarity between neighbouring units synaptic vectors, and, it is interesting distinguish the fact that all the neurons in a cluster have similar synaptic shapes. Furthermore, the integrated information about the distance addition map shows that there is no significant colour variation inside the same cluster. The six component

Figure 5. GCS network trained with multidimensional data of satellite image, 54 output neurons. Graphs from (a) to (f) show the component planes for the six elements of the synaptic vectors. (g) Direct visualization map using distance addition map additional information.

plane graphs exhibit possible dependences involving TM1, TM2 and TM3 input vector components and, TM5 and TM7 components too.

Results

Several Kohonen and GCS networks have been trained in order to evaluate and compare the resulting visualization graphs. For the sake of space only a few of these maps have been included here. Fig. 3 and Fig. 4 compare Kohonen and GCS visualizations using distance map, U-map, distance addition map, data histograms and quantization error map. It can be observed that GCS model offers much better graphical results in clusters analysis than Kohonen networks. The removal of units and connections inside low probability distribution areas causes that GCS network presents within a particular cluster the same quality of information that Kohonen network in relation to the entire map. Since it has already been mentioned, the grey scale used in all the maps is relative to the maximum and minimum values taken by the studied parameter. In all the cases the range of values taken by the calculated factor using GCS is minor than using Kohonen maps.

The exposed visualization methods applied to the visual analysis of multidimensional satellite data has given very satisfactory results (Fig 5). All trained GCS networks have been able to generate six sub maps in the output layer (in some case they have arrived up to eight) that identify the six land cover classes present in the sample of data. The direct visualization map and the component plane graphs have demonstrated to be a useful tool for the extraction of knowledge of the multisensorial data.

FUTURE TRENDS

The proposed knowledge visualization method based on GCS networks has results a useful tool for multidimensional data analysis. In order to evaluate the quality of the trained networks we consider necessary to develop some measure techniques (qualitative and quantitative in numerical and graphical format) to analyze the topology preservation obtained. In this way we will be able to validate the information visualized by the methods presented in this paper.

Also it would be interesting to validate these methods of visualisation with new data sets of very high

dimensional nature. We need to study the viability of cluster analysis with this projection technique when this class of data samples is used.

CONCLUSION

The exposed embedding method allows multidimensional data to be displayed as two-dimensional grey images. The visual-spatial abilities of human observers can explore these graphical maps to extract interrelations and characteristics in the dataset.

In GCS model the networks size does not have to be specified in advance. During the training process, the size of the network grows and decreases adapting its architecture to the particular characteristics of the training dataset.

Although in GCS networks it is necessary to determine a great number of training factors than in Kohonen model, using the learning modified model the tuning of the training factors values is simplified. In fact, several experiments have been made on datasets of diverse nature using the same values for all the training factors and giving excellent results in all the cases.

Especially notable is the cluster detection during the self-organization process without any other additional information.

KEY TERMS

Artificial Neural Networks: An interconnected group of units or neurons that uses a mathematical model for information processing based on a connectionist approach to computation.

Data Mining: The application of analytical methods and tools to data for the purpose of identifying patterns, relationships or obtaining systems that perform useful tasks such as classification, prediction, estimation, or affinity grouping.

Exploratory Data Analysis: Philosophy about how a data analysis should be carried out. Exploratory data analysis employs a variety of techniques (mostly graphical) to extract the knowledge inherent to the data.

Growing Cell Structures: Growing variant of the self-organizing map model, with the peculiarity of dynamically adapts the size and connections of the output layer to the characteristics of the training patterns.

Knowledge Visualization: The creation and communication of knowledge through the use of computer and non-computer-based, complementary, graphic representation techniques.

Self-Organizing Map: A subtype of artificial neural network. It is trained using unsupervised learning to produce low dimensional representation of the training samples while preserving the topological properties of the input space

Unsupervised Learning: Method of machine learning where a model is fit to observations. It is distinguished from supervised learning by the fact that there is no a priori output.

GTM User Modeling for aiGA Weight Tuning in TTS Synthesis

Lluís Formiga

Universitat Ramon Llull, Spain

Francesc Alias

Universitat Ramon Llull, Spain

INTRODUCTION

Unit Selection Text-to-Speech Synthesis (US-TTS) systems produce synthetic speech based on the **retrieval** of previous recorded speech units from a **speech database (corpus)** driven by a weighted cost function (Black & Campbell, 1995). To obtain high quality synthetic speech these **weights must be optimized** efficiently. To that effect, in previous works, a technique was introduced for **weight tuning** based on evolutionary perceptual tests by means of **Active Interactive Genetic Algorithms (aiGAs)** (Alias, Llorà, Formiga, Sastry & Goldberg, 2006) **aiGAs** mine models that map **subjective preferences** from users by **partial ordering graphs, synthetic fitness** and **Evolutionary Computation (EC)** (Llorà, Sastry, Goldberg, Gupta & Lakshmi, 2005). Although **aiGA** propose an effective method to **map single user preferences**, as far as we know, the methodology to extract common solutions among different **individual preferences** (hereafter denoted as *common knowledge*) has not been tackled yet. Furthermore, there is an ambiguity problem to be solved when different users evolve to different weight configurations. In this review, **Generative Topographic Mapping (GTM)** is introduced as a method to extract common knowledge from **aiGA** models obtained from **user preferences**.

BACKGROUND

Weight Tuning in Unit-Selection Text-to-Speech Synthesis

The aim of **US-TTS** is to generate synthetic speech by concatenating the sequence of units that best fit the requirements derived from the input text. The speech

units are retrieved from a **database (speech corpus)** which stores speech-units previously recorded by a professional speaker, typically.

Text-to-speech workflow is generally modelled as two independent blocks that convert written text into speech signal. The first block is named Natural Language Processing (NLP), which is followed by the Digital Signal Processing block (DSP). At first stage, The NLP block carries out a text preprocessing (e.g. conversion of digit numbers or acronyms to words), then it converts graphemes to phonemes. And at last stage, the NLP block assigns quantified prosody parameters to each phoneme guiding the way each phoneme is converted to signal. Generally, this quantified prosody parameters involve duration, pitch and energy. Next, The DSP block retrieves from a recorded **database (speech corpus)** the sequence of units that best matches the target requirements (the phonemes and their prosody). Finally, the speech units are ensembled to obtain the output speech signal.

The **retrieval** process is done by a dynamic programming algorithm (e.g. Viterbi or A* (Formiga & Alias, 2006)) driven by a cost function. The cost function computes the load of **selecting a unit** within a sequence as the sum of two weighted subcosts (see equation (1)): the target subcost (C^t) and the concatenation subcost (C^c). In this work, the C^t is considered as a weighted linear combination of the normalized prosody distances between the target-NLP predicted prosody vector and the candidate unit prosody vector (see equation). Otherwise, the C^c is computed as a weighted linear combination of the distances between the feature vectors of the speech signal around its concatenation point (see equation).

$$C(t_1^n, u_1^n) = \sum_{i=1}^n C^t(t_i, u_i) + \sum_{i=2}^n C^c(u_{i-1}, u_i) \quad (1)$$

$$C^t(t_i, u_i) = \sum_{j=1}^p w_j^t C_j^t(t_i, u_i) \quad (2)$$

$$C^c(u_{i-1}, u_i) = \sum_{j=1}^q w_j^c C_j^c(u_{i-1}, u_i) \quad (3)$$

where t_1^n represents the target units sequence $\{t_1, t_2, \dots, t_n\}$ and u_1^n represents the candidate units sequence $\{u_1, u_2, \dots, u_n\}$.

$$C_j^t(t_i, u_i) = 1 - e^{-\left(\frac{P_j(t_i)}{\sigma_{P_j}}\right)^2} \quad (4)$$

$$C_j^c(u_{i-1}, u_i) = 1 - e^{-\left(\frac{P_j^R(u_{i-1}) - P_j^L(u_i)}{\sigma_{P_j}}\right)^2} \quad (5)$$

Appropriate design of cost function by means of **weight training** is a crucial to earn high quality synthetic speech (Black, 2002). Nevertheless this concern has focused approaches with no unique response. Several techniques have been suggested for **weight tuning**, which may be spitted into three families: *i)* manual-tuning *ii)* computationally-driven purely objective methods and *iii)* perceptually optimized techniques (Alías, Llorà, Formiga, Sastry & Goldberg, 2006). The present review is based on the techniques based on human feedback to the training process, following previous work (Alías, Llorà, Formiga, Sastry & Goldberg, 2006), which is outlined in the next section.

The Approach: Interactive Evolutionary Weight Tuning

Computationally-driven purely objective methods are mainly focused on an acoustic measure (obtained from cepstral distances) between the resynthesized and the natural signals. Hunt and Black adopted two approaches in (Hunt & Black, 1996). The first approach was based on **adjusting the weights** through an exhaustive search of a prediscretized weight space (weight space search, WSS). The second approach proposed by the authors used a multilinear regression technique (MLR), across the entire **database to compute the desired weights**. Later, Meron and Hirose (Meron & Hirose, 1999) presented a methodology that improved the efficiency of the WSS and refined the MLR method. In a previous

work (Alías & Llorà, 2003), introduced **evolutionary computation** to perform this tuning. More precisely, Genetic Algorithms (GA) were applied to obtain the most appropriate weight. The main added value of making use of GA to find optimal weight configuration is the independency to linear search models (as in MLR) and, in addition, it avoids the exhaustive search (as in WSS).

However, all this methods lack on its dependency on the acoustic measure to determine the actual quality of the synthesized speech, which in most part is relative to human hearing. To obtain better speech quality, it was suggested that user should take part in the process. In (Alías, Llorà, Iriondo, Sevillano, Formiga & Socoró, 2004) there were conducted preference tests by synthesizing the training text according to two different weights and comparing the obtained speech subjective quality. Subsequently, **Active Interactive Genetic Algorithms** were presented in (Llorà, Sastry, Goldberg, Gupta & Lakshmi, 2005) as one interactive **evolutionary computation** method where the user feedback evolves the solutions through *survival-of-the-fittest* mechanism. The solutions inherent **fitness** is based on the **partial order** provided by the evaluator; **Active iGAs** base its efficiency on evolving different solutions by means of **surrogate fitness**, which generalize the **user preferences**. This surrogate fitness and the **evolutionary process** are based on the following key elements: *i)* **partial ordering**, *ii)* induced complete order, and *iii)* surrogate function via ε Support Vector Machines (ε -SVM). Preference decisions made by the user are modelled as a **directional graph** which is used to generate partial ordering of solutions (e.g: $\hat{x}_1 > \hat{x}_2; \hat{x}_2 > \hat{x}_3 : \hat{x}_1 \rightarrow \hat{x}_2 \rightarrow \hat{x}_3$) (see figure 1). Table 1 shows the approach of global rank based on dominance measure: given a vertex v , the number of dominated vertexes $\delta(v)$ and dominating vertexes is computed. Using this measures, the estimated fitness may be computed as $\hat{f}(v) = \delta(v) - (v)$. The estimated ranking $\hat{r}(v)$ is obtained by sorting based on $\hat{f}(v)$ (Llorà, Sastry, Goldberg, Gupta & Lakshmi, 2005). The procedure of **aiGA** is detailed in algorithm 1.

However, once the global weights were obtained with **aiGA**, there was no single dominant weight solution (Alías, Llorà, Formiga, Sastry & Goldberg, 2006), i.e. each test performed by different users gave similar and different solutions. This fact implied that a second group of users had to validate the obtained weights.

Figure 1. (Left) Partial evaluations allow building a directed graph among all solutions. (Right) Obtained graph must be cleared to avoid cycles and draws.

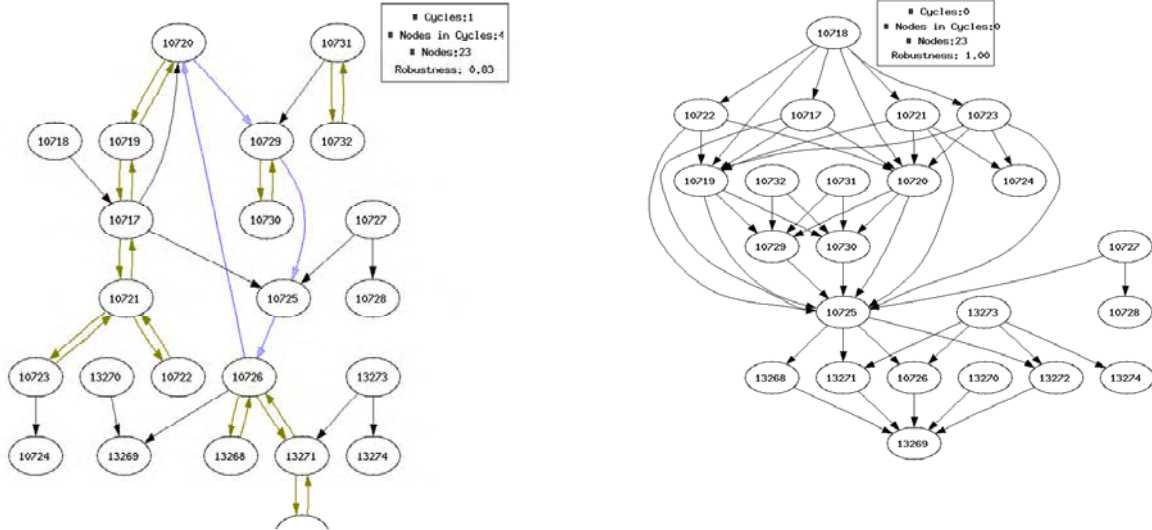

Table 1. Estimation of the global ranking based on the dominance measure. *Dur T Ene T* and *Pit T* stand for the weight values for target weights (duration, energy and pitch). In the same way, *Pit C Ene C* and *Mfc C* stand for the weight values for concatenation weights (Pitch, Energy and Mel Frequency Cepstrum).

| v | $\delta(v)$ | $\phi(v)$ | $\hat{f}(v)$ | Dur T | Ene C | Ene T | Mfc C | Pit C | Pit T | $\hat{r}(v)$ | ε -SVM $\hat{f}(v)$ |
|----------|-------------|-----------|--------------|----------|----------|----------|----------|----------|----------|--------------|---------------------------------|
| 10718 | 15 | 0 | 15 | 0.04 | 0.32 | 0.04 | 0.27 | 0.22 | 0.12 | 1 | (0.189) |
| 10721 | 11 | 1 | 10 | 0.27 | 0.08 | 0.26 | 0.1 | 0.11 | 0.18 | 2.5 | (3.294) |
| 10723 | 11 | 1 | 10 | 0.17 | 0.16 | 0.05 | 0.01 | 0.31 | 0.29 | 2.5 | (3.286) |
| \vdots | \vdots | \vdots | \vdots | \vdots | \vdots | \vdots | \vdots | \vdots | \vdots | \vdots | \vdots |
| 13271 | 1 | 14 | -13 | 0.17 | 0.16 | 0.02 | 0.11 | 0.31 | 0.23 | 21 | (13.091) |
| 13272 | 1 | 14 | -13 | 0.24 | 0.12 | 0.25 | 0.12 | 0.26 | 0.01 | 21 | (20.174) |
| 13269 | 0 | 19 | -19 | 0.01 | 0.21 | 0.01 | 0.17 | 0.32 | 0.27 | 23 | (23.792) |

Thus, clustering problem from different tests was suitable to the **weight tuning** problem with the goal of extracting consistent results from the user tests.

GENERATIVE TOPOGRAPHIC MAPPING BEING A PLUS

GTM in a Nutshell

Unsupervised learning allows to group sparse data into clusters in terms of similarity of data samples. Several

Algorithm 1

methods perform this grouping (Figuereido & Jain, 2002): Expectation Maximization (EM), k-means, Gaussian Mixture Models (GMM), Self Organizing Maps (SOM) and **Generative Topographic Mapping**, among others.

Techniques may be grouped, according to (Figuereido & Jain, 2002), into two types of formulation: *i*) model-based methods (e.g. GMM, EM, **GTM**) and *ii*) heuristic methods (e.g. k-means or hierarchical agglomerative methods). The number of sources generating the data is the differential propriety. Indeed, model-based methods suppose that the observations have been fashioned by one (arbitrarily chosen and unidentified) source of a set of alternative arbitrary sources. Therefore, inferring these tuned sources and mapping the source to each observation leads to a clustering of the set of observations. Otherwise, heuristic methods assume only one source for the observed data considering similar heterogeneity for them.

Self-Organizing Maps (or Kohonen maps) (Kohonen, 1990) are a clustering technique based on neural networks. The easiness of visualizing of multidimen-

sional data is the largely appropriate added value of SOM. In addition, **Generative Topographic Mapping** is a nonlinear latent variable model introduced in (Bishop, Svensen & Williams, 1998). **GTM** intends to give an substitute answer to SOM by means of overcoming its restrictions which are listed in (Kohonen, 2006): *i*) the absence of a cost function, *ii*) the lack of a theoretical basis for choosing learning rate parameter schedules and neighbourhood parameters to ensure topographic ordering, *iii*) the absence of any general proofs of convergence and *iv*) the fact that the model does not define a probability density.

GTM is based on a constrained mixture of GMM whose parameters can be tuned through EM algorithm. The handicap of heuristic based models is that there is not *a-priori* distribution of the centroids for each cluster. In **GTM**, the set of latent points is modelled as a grid. A circular gaussian distribution is a point in the grid with its equivalent correspondence, through a weighted non-linear basis functions, onto the multidimensional space. Thus, grid is shaped to wrap the data due to the explicit order among the gaussian distributions

Modelling User Preferences by GTM

GTM is able to extract solutions from the different **aiGA** evolved graphs due to the consistency of its theoretical basis. The key objective is to recognize important clusters inside the evolved data space and therefore, determine the fitness entropy of each cluster in terms of fitness variance to choose the global weight configuration set.

GTM can model the best **aiGA** weights from multi-dimensional weight space into a two-dimensional space. Taking into account the cluster with higher averaged fitness and lower standard deviation allows selecting the best weight configuration from different user **aiGA** models. For adjusting this method the geometry of the gaussian distributions and the size of the latent space have to be set up manually. EM weights **GTM** centroids and the basis functions. Then, it is extracted from each cluster the average fitness as well as its standard deviation. The computation of the averaged fitness and standard deviation is computed from the set which its weight combinations bayesian *a posteriori* probability is the highest to the cluster.

It is to note that the **fitness** itself does not get involved into the optimization EM part on behalf it is relative to each user and is not known for unevaluated weight combinations for one specific user (unless ϵ -SVM predicted).

Experiments and Results

On (Formiga & Alías, 2007) common knowledge was extracted from user **evolved weights** from previous tests conducted on catalan **speech corpus** with 9863 recorded units (1207 diphones and triphones) (obtained from 1520 sentences and words) (Alías, Llorà, Formiga, Sastry & Goldberg., 2006). On that test, five phonetically balanced sentences were extracted from the **corpus** to perform the global **weight tuning** process by a web interface named SinEvo (Alías, Llorà, Iriundo, Sevillano, Formiga & Socoró, 2004). The evolved weights were normalized through Max-Min normalization to range all weights between 0 and 1. That test was conducted by three users, obtaining fifteen different weight configurations.

Figure 2. Performance of GTM: Different pareto fronts were analyzed for each configuration

On (Formiga & Alias, 2007), different configurations of **GTM** were analyzed for **mapping normalized weights** (hexagonal or rectangular grid and different grid sizes: $(3 \times 3, 4 \times 4, 5 \times 5)$). The purpose of this analysis was to find the optimal **GTM** configuration, i.e. The one which minimizes averaged standard deviation (std) per cluster and the number of significant clusters per population (with averaged fitness over 75%) while maximizing the averaged mean fitness per cluster. As it may be noticed in figure 2, the 4×4 grid configuration with hexagonal latent grid was selected as it yielded the best Pareto front (although the rest of 4×4 grids achieved similar performance).

After **GTM** was set up, each evolved weights were extracted and mapped to other users **GTM**s within the same sentence, obtaining their corresponding fitness from the other **users preferences**. Equation 6 allowed to set a global fitness (gF) from overall averaged fitness (F_{Av}^{GTM}) for each evolved weight configuration.

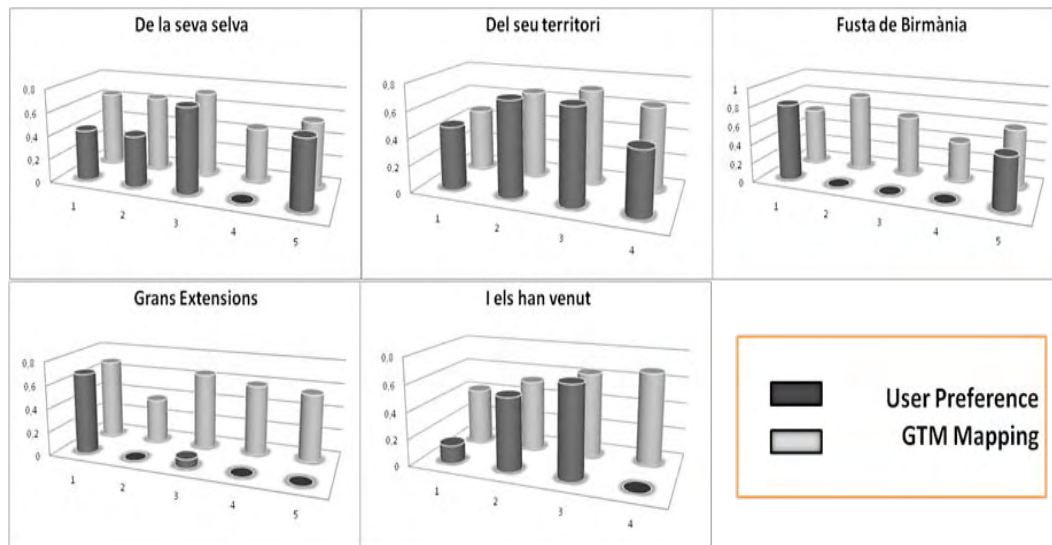

$$gF_{w_i} = \frac{1}{N} \cdot \sum_{i=1}^U \sum_{j=1}^W F_{Av}^{GTM}(w_j, u_i) \quad (6)$$

where U stands for the number of users, W for the number of weight configurations, N stands for the total number of weights ($U + W$).

In addition, to avoid a perceptual manual validation stage ten different users-not involved whatsoever in the tuning process-performed a comparison to the aIGA best weights to allow a comparison between **GTM** clustering and real human preference on validation stage.

Analyzing the results on figure 3, the **GTM** most voted weights configurations fit in with the manual **user preferences** for three sentences (*De la Seva Selva*, *Del seu Territori* and *Grans Extensions*). Though, the rest of the sentences have quite different behaviour. The best weight combination selected from the users was the second **GTM** best weight configuration in *I els han venut* while the best **GTM** weight combination was never been voted. Cosine correlation is taken into account among problematic weights configurations as the important matter is weight distribution instead of analyzing the values themselves. In this case, **GTM** two better weights have a 0.7841 correlation, so **GTM** results may be measured satisfactory as weights approach equivalent patterns. By the other hand, the correlation

Figure 3. The results of the comparison between normalized user voted preferences and GTM mapping are presented for the five sentences. Two different solutions for same user were considered if they adopted similar fitness in aIGA model.

between the two best **GTM** weights configurations is 0.8323 in *Fusta de Birmània* and, as in the previous case, the correlation gives again satisfactory results.

FUTURE TRENDS

Future work will be focused on conducting new experiments, e.g. by clustering similar units instead of tackling global **weight tuning** on preselected sentences or by including more users in the training process. In addition the expansion of the capabilities of **GTM** to **map user preferences** opens the possibility to focus on non-linear cost functions so as to overcome the linearity restrictions of the present function.

CONCLUSIONS

This article continues the work of including **user preferences** for tuning the weights of the cost function in **Unit-selection TTS** systems. In previous works we have presented a method to find cost function optimal weight tuning based on perceptual criteria of individual users. As a next step, this paper applies a heuristic method for choosing the best solution among all users overcoming the need to conduct a second listening test to select the best weight configuration among individual optimal solutions. This proof-of-principle study shows that **GTM** is capable of **mapping the common knowledge** among different users thanks to working on the perceptually optimized weights space obtained through **aiGA** and getting a final solution that can be used for a final adjustment of the **TTS**.

KEY TERMS

Correlation: A statistical measurement of the interdependence or association between two or qualitative variables. A typical calculation would be performed by multiplying a signal by either another signal (cross-correlation) or by a delayed version of itself (autocorrelation).

Digital Signal Processing (DSP): DSP, or Digital Signal Processing, as the term suggests, is the processing of signals by digital means. The processing of a digital signal is done by performing numerical calculations.

Diphone: A sound consisting of two phonemes: one that leads into the sound and one that finishes the sound. e.g.: “hello” silence-h h-eh eh-l l-oe oe-silence.

Evolutionary Algorithms: Collective term for all variants of (probabilistic) optimization and approximation algorithms that are inspired by Darwinian evolution. Optimal states are approximated by successive improvements based on the variation-selection-paradigm.

Generative Topographic Mapping (GTM): It is a technique for density modelling and data visualisation inspired in SOM (see SOM definition).

Mel Frequency Cepstral Coefficients (MFCC): The MFCC are the coefficients of the Mel cepstrum. The Mel-cepstrum is the cepstrum computed on the Mel-bands (scaled to human ear) instead of the Fourier spectrum.

Natural Language Processing (NLP): Computer understanding, analysis, manipulation, and/or generation of natural language.

Pitch: Intonation measure given a time in the signal.

Prosody: A collection of phonological features including pitch, duration, and stress, which define the rhythm of spoken language.

Text Normalization: The process of converting abbreviations and non-word written symbols into words that a speaker would say when reading that symbol out loud.

Unit Selection Synthesis: A synthesis technique where appropriate units are retrieved from **large databases** of natural speech so as to generate synthetic speech.

Unsupervised Learning: Learning techniques that group instances without a pre-specified dependent attribute. Clustering algorithms are usually unsupervised methods for grouping data sets.

Self-Organizing Maps: Self-organizing maps (SOMs) are a data visualization technique which reduce the dimensions of data through the use of self-organizing neural networks

Surrogate Fitness: Synthetic fitness measure that tries to evaluate one evolutionary solution in the same terms as one perceptual user would

Handling Fuzzy Similarity for Data Classification

Roy Gelbard

Bar-Ilan University, Israel

Avichai Meged

Bar-Ilan University, Israel

INTRODUCTION

Representing and consequently processing fuzzy data in standard and binary databases is problematic. The problem is further amplified in binary databases where continuous data is represented by means of discrete '1' and '0' bits. As regards classification, the problem becomes even more acute. In these cases, we may want to group objects based on some fuzzy attributes, but unfortunately, an appropriate fuzzy similarity measure is not always easy to find. The current paper proposes a novel model and measure for representing fuzzy data, which lends itself to both classification and data mining.

Classification algorithms and data mining attempt to set up hypotheses regarding the assigning of different objects to groups and classes on the basis of the similarity/distance between them (Estivill-Castro & Yang, 2004) (Lim, Loh & Shih, 2000) (Zhang & Srihari, 2004). Classification algorithms and data mining are widely used in numerous fields including: social sciences, where observations and questionnaires are used in learning mechanisms of social behavior; marketing, for segmentation and customer profiling; finance, for fraud detection; computer science, for image processing and expert systems applications; medicine, for diagnostics; and many other fields.

Classification algorithms and data mining methodologies are based on a procedure that calculates a similarity matrix based on similarity index between objects and on a grouping technique. Researches proved that a similarity measure based upon binary data representation yields better results than regular similarity indexes (Erllich, Gelbard & Spiegler, 2002) (Gelbard, Goldman & Spiegler, 2007). However, binary representation is currently limited to nominal discrete attributes suitable for attributes such as: gender, marital

status, etc., (Zhang & Srihari, 2003). This makes the binary approach for data representation unattractive for widespread data types.

The current research describes a novel approach to binary representation, referred to as Fuzzy Binary Representation. This new approach is suitable for all data types - nominal, ordinal and as continuous. We propose that there is meaning not only to the actual explicit attribute value, but also to its implicit similarity to other possible attribute values. These similarities can either be determined by a problem domain expert or automatically by analyzing fuzzy functions that represent the problem domain. The added new fuzzy similarity yields improved classification and data mining results. More generally, Fuzzy Binary Representation and related similarity measures exemplify that a refined and carefully designed handling of data, including eliciting of domain expertise regarding similarity, may add both value and knowledge to existing databases.

BACKGROUND

Binary Representation

Binary representation creates a storage scheme, wherein data appear in binary form rather than the common numeric and alphanumeric formats. The database is viewed as a two-dimensional matrix that relates entities according to their attribute values. Having the rows represent entities and the columns represent possible values, entries in the matrix are either '1' or '0', indicating that a given entity (e.g., record, object) has or lacks a given value, respectively (Spiegler & Maayan, 1985).

In this way, we can have a binary representation for discrete and continuous attributes.

Table 1. Standard binary representation table

| Entity ID | Regular Representation | | Binary Representation | | | | | | | |
|-----------|------------------------|--------|-----------------------|---|---|---|------|------|------|------|
| | Marital Status | Height | S | M | D | W | 1.55 | 1.56 | 1.60 | 1.84 |
| 1 | Married | 1.60 | 0 | 1 | 0 | 0 | 0 | 0 | 1 | 0 |
| 2 | Divorced | 1.55 | 0 | 0 | 1 | 0 | 1 | 0 | 0 | 0 |
| 3 | Single | 1.84 | 1 | 0 | 0 | 0 | 0 | 0 | 0 | 1 |
| 4 | Widowed | 1.56 | 0 | 0 | 0 | 1 | 0 | 1 | 0 | 0 |
| 5 | Single | 1.60 | 1 | 0 | 0 | 0 | 0 | 0 | 1 | 0 |

Table 1 illustrates binary representation of a database consists of five entities with the following two attributes: Marital Status (nominal) and Height (continuous).

- Marital Status, with four values: **S** (single), **M** (married), **D** (divorced), **W** (widowed).
- Heights, with four values: **1.55**, **1.56**, **1.60** and **1.84**.

However, practically, binary representation is currently limited to nominal discrete attributes only. In the current study, we extend the binary model to include continuous data and fuzzy representation.

Similarity Measures

Similarity/distance measures are essential and at the heart of all classification algorithms. The most commonly-used method for calculating similarity is the Squared Euclidean measure. This measure calculates the distance between two samples as the square root of the sums of all squared distances between their properties (Jain & Dubes, 1988) (Jain, Murty & Flynn, 1999).

However, these likelihood-similarity measures are applicable only to ordinal attributes and cannot be used to classify nominal, discrete, or categorical attributes, since there is no meaning in placing such attribute values in a common Euclidean space. A similarity measure, which applicable to nominal attributes and used in our research is the Dice (Dice 1945).

Additional binary similarity measures were developed and presented (Illingworth, Glaser & Pyle, 1983) (Zhang & Srihari, 2003). Similarities measures between the different attribute values, as proposed in

Zadeh (1971) model, are essential in the classification process.

In the current study we use similarities between entities and between entity's attribute values to get better classification. Following former reserches, (Gelbard & Spiegler, 2000) (Erlich, Gelbard & Spiegler, 2002), the current study also uses Dice measure.

Fuzzy Logic

The theory of Fuzzy Logic was first introduced by Lotfi Zadeh (Zadeh, 1965). In classical logic, the only possible *truth-values* are *true* and *false*. In Fuzzy Logic; however, more *truth-values* are possible beyond the simple true and false. Fuzzy logic, then, derived from fuzzy set theory, is designed for situations where information is inexact and traditional digital on/off decisions are not possible.

Fuzzy sets are an extension of classical set theory and are used in fuzzy logic. In classical set theory, membership of elements in relation to a set is assessed according to a clear condition; an element either belongs or does not belong to the set. By contrast, fuzzy set theory permits the gradual assessment of the membership of elements in relation to a set; this is described with the aid of a membership function $\mu \rightarrow [0, 1]$. An element mapped to the value 0 means that the member is not included in the given set, '1' describes a fully included member, and all values between 0 and 1 characterize the fuzzy members. For example, the continuous variable "Height" may have three membership functions; stand for "Short", "Medium" and "Tall" categories. An object may belong to few categories in different membership degree, e.g 180 cm. height may belong to the "Medium" and "Tall" categories, in different

membership degree expressed by the range $[0,1]$. The membership degrees are returned from the membership functions. We can say that a man whose height is 180 cm. is “slightly medium” and a man whose height is 200 cm. is of “perfect tall” height.

Different membership functions might represent different membership degrees. Having several possibilities for membership functions is part of the theoretical and practical drawbacks in Zada’s model. There is no “right way” to determine the right membership functions (Mitaim & Kosko, 2001). Thus, a membership function may be considered arbitrary and subjective.

In the current work, we make use of membership functions to develop the enhanced similarity calculation for use in classification of fuzzy data.

FUZZY SIMILARITY REPRESENTATION

Standard Binary Representation exhibits data integrity in that it is precise, and preserves data accuracy without either loss of information or rounding of any value. The mutual exclusiveness assumption causes the “isolation” of each value. This is true for handling discrete data values. However, in dealing with a continuous attribute, e.g. Height, we want to assume that height 1.55 is closer to 1.56 than to 1.60. However, when converting such values into a mutually exclusive binary representation (Table 1), we lose these basic numerical relations. Similarity measures between any pair with different attribute values is always 0, no matter how similar the attribute values are. This drawback makes the standard binary representation unattractive for representing and handling continuous data types.

Similarity between attribute values is also needed for nominal and ordinal data. For example, the color “red” (nominal value) is more similar to the color “purple” than it is to the color “yellow”. In ranking (question-

naires) a “1” satisfactory rank (ordinal variable) might be closer to the “2” rank than to the “5” rank.

The absence of these similarity “intuitions” are of paramount importance in classification and indeed may cause some inaccuracies in classification results.

The following sections present a model that adds relative similarity values to the data representation. This serves to empower the binary representation to better handle both continuous and fuzzy data and improves classification results for all attribute types.

Model for Fuzzy Similarity Representation

In standard binary representation, each attribute (which may have several values, e.g., color: red, blue, green, etc.) is a vector of bits where only one bit is set to “1” and all others are set to “0”. The “1” bit stands for the actual value of the attribute. In the Fuzzy Binary Representation, the zero bits are replaced by relative similarity values.

The Fuzzy Binary Representation is viewed as a two-dimensional matrix that relates entities according to their attribute values. Having the rows represent entities and the columns represent possible values, entries in the matrix are fuzzy numbers in the range $[0,1]$, indicating the similarity degree of specific attribute value to the actual one, where ‘1’ means full similarity to the actual value (this is the actual value), ‘0’ means no similarity at all and all other values means partial similarity.

The following example illustrates the way for creating the Fuzzy Binary Representation: Let’s assume we have a database of five entities and two attributes represented in a binary representation as illustrated in Table 1. The fuzzy similarities between all attribute values are calculated (next section describes the calculation process) and represented in a two-dimensional “Fuzzy

Table 2. Fuzzy similarity matrixes of the marital status and height attributes

| Marital Status | S | M | D | W |
|----------------|-----|---|-----|-----|
| S | 1 | 0 | 0.6 | 0.8 |
| M | 0 | 1 | 0 | 0 |
| D | 0.6 | 0 | 1 | 0.5 |
| W | 0.8 | 0 | 0.5 | 1 |

| Height | 1.55 | 1.56 | 1.60 | 1.84 |
|--------|------|------|------|------|
| 1.55 | 1 | 0.9 | 0.7 | 0 |
| 1.56 | 0.9 | 1 | 0.8 | 0 |
| 1.60 | 0.7 | 0.8 | 1 | 0 |
| 1.84 | 0 | 0 | 0 | 1 |

Similarity Matrix”, wherein rows and columns stand for the different attributes’ values, and the matrix cells contain the fuzzy similarity between the value pairs. The Fuzzy Similarity Matrix is symmetrical. Table 2 illustrates fuzzy similarity matrixes for Marital Status and Height attributes.

The Marital Status similarity matrix shows that the similarity between Single and Widow is “high” (0.8), while there is no similarity between Single and Married (0). The Height similarity matrix shows that the similarity between 1.56 and 1.60 is 0.8 (“high” similarity), while the similarity between 1.55 and 1.84 is 0 (not similar at all). These similarity matrixes can be calculated automatically, as is explained in the next section.

Now, the zero values in the binary representation (Table 1) are replaced by the appropriate similarity value (Table 2). For example, in Table 1, we will replace the zero-bit stands for Height 1.55 of the first entity, with the fuzzy similarity between 1.55 and 1.60 (the actual attribute value), as indicated in the Height fuzzy similarity matrix (0.7). Table 3 illustrates the fuzzy representation accepted after such replacements.

It should be noted that the similarities indicated in the fuzzy similarity table relate to the similarity between the actual value of the attribute (e.g. 1.60 in

entity 1) and the other attributes’ values (e.g. 1.55, 1.56 and 1.84).

Next, the fuzzy similarities, presented in decimal form, are converted into a binary format – the Fuzzy Binary Representation. The conversion should allow similarity indexes like Dice.

To meet this requirement, each similarity value is represented by N binary bits, where N is determined by the required precision. For one- tenth precision, 10 binary bits are needed, for one-hundredth precision, 100 binary bits are needed. For ten bits precision fuzzy similarity “0” will be represented by ten ‘0’s, the fuzzy similarity “0.1” will be represented by nine ‘0’ followed by one ‘1’, the fuzzy similarity “0.2” will be represented by eight ‘0’s followed by two ‘1’s and so on till the fuzzy similarity “1” which will be represented by ten ‘1’s. Table 4 illustrates the conversion from fuzzy representation (Table 3) to fuzzy binary representation.

The Fuzzy Binary Representation illustrated in Table 4 is suitable for all data types (discrete and continuous) and, with the new knowledge (fuzzy similarities values) it contains, a better classification is expected.

The following section describes the process for similarity calculations necessary for this type of Fuzzy Binary Representation.

Table 3. Fuzzy similarity table

| ID | Marital Status | | | | Height | | | |
|----|----------------|---|-----|-----|--------|------|------|------|
| | S | M | D | W | 1.55 | 1.56 | 1.60 | 1.84 |
| 1 | 0 | 1 | 0 | 0 | 0.7 | 0.8 | 1 | 0 |
| 2 | 0.6 | 0 | 1 | 0.5 | 1 | 0.9 | 0.7 | 0 |
| 3 | 1 | 0 | 0.6 | 0.8 | 0 | 0 | 0 | 1 |
| 4 | 0.8 | 0 | 0.5 | 1 | 0.9 | 1 | 0.8 | 0 |
| 5 | 1 | 0 | 0.6 | 0.8 | 0.7 | 0.8 | 1 | 0 |

Table 4. Fuzzy binary representation table

| ID | Marital Status | | | | Height | | | |
|----|----------------|------------|------------|------------|------------|------------|------------|------------|
| | S | M | D | W | 1.55 | 1.56 | 1.60 | 1.84 |
| 1 | 0000000000 | 1111111111 | 0000000000 | 0000000000 | 0001111111 | 0011111111 | 1111111111 | 0000000000 |
| 2 | 0000111111 | 0000000000 | 1111111111 | 0000011111 | 1111111111 | 0111111111 | 0001111111 | 0000000000 |
| 3 | 1111111111 | 0000000000 | 0000111111 | 0011111111 | 0000000000 | 0000000000 | 0000000000 | 1111111111 |
| 4 | 0011111111 | 0000000000 | 0000011111 | 1111111111 | 0111111111 | 1111111111 | 0011111111 | 0000000000 |

Fuzzy Similarity Calculation

Similarity calculation between the different attribute values is not a precise science, i.e., there is no one way to calculate it, just as there is no one way to develop membership functions in the Fuzzy Logic world.

We suggest determining similarities according to the **attribute type**. A domain expert should evaluate similarity for nominal attributes like “Marital Status”. For example, Single, Divorced and Widowed are considered “one person”, while Married is considered as “two people”. Therefore, Single may be more similar to Divorced and Widowed than it is to Married. On the other hand “Divorced” is one that once was married, so may be it is more similar to Married than to single. In short, similarity is a **relative**, rather than an absolute measure, as there is hardly any known automatic way to calculate similarities for such attributes and therefore a domain expert is needed.

Similarity for ordinal data like satisfactory rank can be calculated in the same way as for nominal or continuous attributes depending on the nature of attributes’ values. Similarity for continuous data like Height can be calculated automatically. Unlike nominal attributes, in continuous data there is an intuitive meaning to the “distance” between different values. For example, as regards the Height attribute, the difference between 1.55 and 1.56 is smaller than the distance between 1.55 and 1.70; therefore, the similarity is expected to be higher accordingly. For continuous data, an automatic method can be constructed, as showed, to calculate the similarities.

Depending on the problem domain, a continuous attribute can be divided into one or more fuzzy sets (categories), e.g., the Height attribute can be divided into three sets: Short, Medium and Tall. A membership function for each set can be developed.

The calculated similarities depend on the specified membership functions; therefore, they are referred to here as fuzzy similarities. The following algorithm can be used for similarity calculations of continuous data:

For each pair of attribute values (v1 and v2)

For each membership function F

*Similarities (v1, v2) = 1 - distance
between F(v1) and F(v2)*

*Similarity (v1, v2) = Maximum of
the calculated Similarities*

Now that we have discussed both a model for Fuzzy Binary Representation and a way to calculate similarities, we will show the new knowledge (fuzzy similarities) added to the standard binary representation improve the similarity measures between different entities, as discussed in the next section.

COMPARING STANDARD AND FUZZY SIMILARITIES

In this section, we compare standard and fuzzy similarities. The similarities were calculated according to the Dice index for the example represented in Table 4.

Table 5 combines similarities of the different entities related to (a) Marital Status (nominal), to (b) Height (continuous) and to (c) both the Marital Status and Height attributes.

Several points and findings arise from the representations shown above (Table 5). These are briefly highlighted below:

1. In our small example, a nominal attribute (Marital Status) represented in standard binary representation cannot be used for classification. In contrast, the Fuzzy Binary Representation, with a large diversity of similarities results, will enable better classification. Grouping entities with a similarity that is equal to or greater than 0.7 yields a class of entities 2, 3, 4 and 5, which represent Single, Divorced and Widowed that belong to the set “one person”.
2. For a continuous attribute (Height) represented in the standard binary representation, classification is not possible. In contrast, the Fuzzy Binary Representation with diversity in similarities results will, once again, enable better classification. Entities 1 and 5 have absolute similarity (1), since for the Height attribute they are identical. Entities 2 and 4 (similarity = 0.94) are very similar, since they represent the almost identical heights of 1.55 and 1.56, respectively. Classification based on these two entities is possible due to diversity of similarities.
3. The same phenomena presented for a single attribute (Marital Status or Height) exist also for the both attributes (Marital Status + Height) when are taking together. Similarity greater than 0.8 is

Table 5. Entities similarity

| Entity ID | | Marital Status | | Height | | (a) Similarity for Marital Status | | (b) Similarity for Height | | (c) Similarity for Marital Status + Height | |
|-----------|---|----------------|---|--------|------|-----------------------------------|-------|---------------------------|-------|--|-------|
| A | B | A | B | A | B | Standard | Fuzzy | Standard | Fuzzy | Standard | Fuzzy |
| 1 | 2 | M | D | 1.60 | 1.55 | 0 | 0 | 0 | 0.86 | 0 | 0.53 |
| 1 | 3 | M | S | 1.60 | 1.84 | 0 | 0 | 0 | 0 | 0 | 0 |
| 1 | 4 | M | W | 1.60 | 1.56 | 0 | 0 | 0 | 0.88 | 0 | 0.54 |
| 1 | 5 | M | S | 1.60 | 1.60 | 0 | 0 | 1 | 1 | 0.5 | 0.59 |
| 2 | 3 | D | S | 1.55 | 1.84 | 0 | 0.75 | 0 | 0 | 0 | 0.41 |
| 2 | 4 | D | W | 1.55 | 1.56 | 0 | 0.72 | 0 | 0.94 | 0 | 0.84 |
| 2 | 5 | D | S | 1.55 | 1.60 | 0 | 0.75 | 0 | 0.86 | 0 | 0.81 |
| 3 | 4 | S | W | 1.84 | 1.56 | 0 | 0.89 | 0 | 0 | 0 | 0.50 |
| 3 | 5 | S | S | 1.84 | 1.60 | 1 | 1 | 0 | 0 | 0.5 | 0.57 |
| 4 | 5 | W | S | 1.56 | 1.60 | 0 | 0.89 | 0 | 0.88 | 0 | 0.88 |

used to group entities 2, 4 and 5, which represent “one person” around 1.56 meters height.

Two important advantages of the novel Fuzzy Binary Representation detailed in the current work over the standard binary representation are suggested: (1) It is practically suitable to all attribute types. (2) It improves classification results.

FUTURE TRENDS

The current work improves classification by adding new similarity knowledge to the standard representation of data. Further research can be conducted to calculate the interrelationship between the different attributes, i.e., the cross-similarities among attributes such as marital status and height. Understanding such interrelationships might further serve to refine the classification and data mining results.

Another worthwhile research direction is helping the human domain expert to get the “right” similarities, and thus choose the “right” membership functions. A Decision Support System may provide a way in which to structure the similarity evaluation of the expert and make his/her decisions less arbitrary.

CONCLUSION

In the current paper, the problems of representing and classifying data in databases were addressed. The focus was on Binary Databases, which have been shown in recent years to have an advantage in classification and data mining. Novel aspects for representing fuzziness were shown and a measure of similarity for fuzzy data was developed and described. Such measures are required, as similarity calculations are at the heart of any classification algorithm. Classification examples were illustrated.

The evaluating of similarity measures shows that standard binary representation is useless when dealing with continuous attributes for classification. Fuzzy Binary Representation reforms this drawback and results in promising classification based on continuous data attributes. In addition, adding fuzzy similarity was also shown to be useful for regular (nominal, ordinal) data to ensure better classification. Summarily, fuzzy representation improves classification results for all attribute types.

KEY TERMS

Classification: The partitioning of a data set into subsets, so that the data in each subset (ideally) share some common traits - often proximity according to some defined similarity/distance measure.

Data Mining: The process of automatically searching large volumes of data for patterns, using tools such as classification, association rule mining, clustering, etc.

Database Binary Representation: A representation where a database is viewed as a two-dimensional matrix that relates entities (rows) to attribute values (columns). Entries in the matrix are either '1' or '0', indicating that a given entity has or lacks a given value.

Fuzzy Logic: An extension of Boolean logic dealing with the concept of partial truth. Fuzzy logic replaces Boolean truth values (0 or 1, black or white, yes or no) with degrees of truth.

Fuzzy Set: An extension of classical set theory. Fuzzy set theory used in Fuzzy Logic, permits the gradual assessment of the membership of elements in relation to a set.

Membership Function: The mathematical function that defines the degree of an element's membership in a fuzzy set. Membership functions return a value in the range of [0,1], indicating membership degree.

Similarity: A numerical estimate of the difference or distance between two entities. The similarity values are in the range of [0,1], indicating similarity degree.

Harmony Search for Multiple Dam Scheduling

Zong Woo Geem

Johns Hopkins University, USA

H

INTRODUCTION

The dam is the wall that holds the water in, and the operation of multiple dams is complicated decision-making process as an optimization problem (Oliveira & Loucks, 1997). Traditionally researchers have used mathematical optimization techniques with linear programming (LP) or dynamic programming (DP) formulation to find the schedule.

However, most of the mathematical models are valid only for simplified dam systems. Accordingly, during the past decade, some meta-heuristic techniques, such as genetic algorithm (GA) and simulated annealing (SA), have gathered great attention among dam researchers (Chen, 2003) (Esat & Hall, 1994) (Wardlaw & Sharif, 1999) (Kim, Heo & Jeong, 2006) (Teegavarapu & Simonovic, 2002).

Lately, another metaheuristic algorithm, harmony search (HS), has been developed (Geem, Kim & Loganathan, 2001) (Geem, 2006a) and applied to various artificial intelligent problems, such as music composition (Geem & Choi, 2007) and Sudoku puzzle (Geem, 2007).

The HS algorithm has been also applied to various engineering problems such as structural design (Lee & Geem, 2004), water network design (Geem, 2006b), soil stability analysis (Li, Chi & Chu, 2006), satellite heat pipe design (Geem & Hwangbo, 2006), offshore structure design (Ryu, Duggal, Heyl & Geem, 2007), grillage system design (Erdal & Saka, 2006), and hydrologic parameter estimation (Kim, Geem & Kim, 2001). The HS algorithm could be a competent alternative to existing metaheuristics such as GA because the former overcame the drawback (such as building block theory) of the latter (Geem, 2006a).

To test the ability of the HS algorithm in multiple dam operation problem, this article introduces a HS model, and applies it to a benchmark system, then compares the results with those of the GA model previously developed.

BACKGROUND

Before this study, various researchers have tackled the dam scheduling problem using phenomenon-inspired techniques.

Esat and Hall (1994) introduced a GA model to the dam operation. They compared GA with the discrete differential dynamic programming (DDDP) technique. GA could overcome the drawback of DDDP which requires exponentially increased computing burden. Oliveira and Loucks (1997) proposed practical dam operating policies using enhanced GA (real-code chromosome, elitism, and arithmetic crossover). Wardlaw and Sharif (1999) tried another enhanced GA schemes and concluded that the best GA model for dam operation can be composed of real-value coding, tournament selection, uniform crossover, and modified uniform mutation. Chen (2003) developed a real-coded GA model for the long-term dam operation, and Kim et al. (2006) applied an enhanced multi-objective GA, named NSGA-II, to the real-world multiple dam system. Teegavarapu and Simonovic (2002) used another metaheuristic algorithm, simulated annealing (SA), to solve the dam operation problem.

Although several metaheuristic algorithms have been already applied to the dam scheduling problem, the recently-developed HS algorithm was not applied to the problem before. Thus, this article deals with the HS algorithm's pioneering application to the problem.

HARMONY SEARCH MODEL AND APPLICATION

This article presents two major parts. The first part explains the structure of the HS model; and the second part applies the HS model to a bench-mark problem.

Dam Scheduling Model Using HS

The HS model has the following formulation for the multiple dam scheduling.

Maximize the benefits obtained by hydropower generation and irrigation

Subject to the following constraints:

1. **Range of Water Release:** the amount of water release in each dam should locate between minimum and maximum amounts.
2. **Range of Dam Storage:** the amount of dam storage in each dam should locate between minimum and maximum amounts.
3. **Water Continuity:** the amount of dam storage in next stage should be the summation of the amount in current stage, the amount of inflow, and the amount of water release.

The HS algorithm starts with filling random scheduling vectors in the harmony memory (HM). The structure of HM for the dam scheduling is as follows:

$$\begin{bmatrix} R_1^1 & R_2^1 & \dots & R_N^1 & Z(\mathbf{R}^1) \\ R_1^2 & R_2^2 & \dots & R_N^2 & Z(\mathbf{R}^2) \\ \vdots & \dots & \dots & \dots & \vdots \\ R_1^{HMS} & R_2^{HMS} & \dots & R_N^{HMS} & Z(\mathbf{R}^{HMS}) \end{bmatrix} \quad (1)$$

Each row stands for each solution vector, and each column stands for each decision variable (water release amount in each stage and each dam). At the end of each row, the objective function value locates. HMS (harmony memory size) is the number of solution vectors is HM.

Based on the initial HM, a new scheduling can be generated with the following function:

$$R_i^{NEW} \leftarrow \begin{cases} R_i, R_i^{MIN} \leq R_i \leq R_i^{MAX} & \text{w.p. } p_1 \\ R_i(k) \in \{R_i^1, R_i^2, \dots, R_i^{HMS}\} & \text{w.p. } p_2 \\ R_i(k) + \Delta & \text{w.p. } p_3 \\ R_i(k) - \Delta & \text{w.p. } p_4 \end{cases} \quad (2)$$

where R_i^{NEW} is a new water release amount for decision variable i ; the first row in the right hand side means that the new amount is chosen randomly from the total range; the second row means that the new amount is chosen from the HM; the third and fourth rows means that the new amount is certain unit (Δ) higher or lower

than the original amount $R_i(k)$ obtained from the HM. The summation of probability is equal to one ($p_1 + p_2 + p_3 + p_4 = 1$).

If the newly-generated vector, \mathbf{R}^{NEW} , is better than the worst harmony in the HM in terms of objective function, the new harmony is included in the HM and the existing worst harmony is excluded from the HM.

If the HS model reaches MaxImp (maximum number of function evaluations), computation is terminated. Otherwise, another new harmony (= vector) is generated by considering one of three above-mentioned mechanisms.

Applying HS to a Benchmark Problem

The HS model was applied to a popular multiple dam system as shown in Figure 1 (Wardlaw & Sharif, 1999).

The problem has 12 two-hour operating periods, and only dam 4 has irrigation benefit because outflows of other dams are not directed to farms. The range of water releases is as follows:

$$0.0 \leq R_1 \leq 3, 0.0 \leq R_2, R_3 \leq 4, 0.0 \leq R_4 \leq 7 \quad (3)$$

The range of dam storages is as follows:

Figure 1. Schematic of four dam system

$$0.0 \leq S_1, S_2, S_3 \leq 10, 0.0 \leq S_4 \leq 15$$

(4)

$$S_1(0), S_2(0), S_3(0), S_4(0) = 5$$

(5)

The initial and final storage conditions are as follows:

$$S_1(12), S_2(12), S_3(12) = 5, S_4(12) = 7$$

(6)

Table 1. One example of optimal schedules by HS

| Time | Dam 1 | Dam 2 | Dam 3 | Dam 4 |
|------|-------|-------|-------|-------|
| 0 | 1.0 | 4.0 | 0.0 | 0.0 |
| 1 | 0.0 | 1.0 | 0.0 | 2.0 |
| 2 | 0.0 | 2.0 | 4.0 | 7.0 |
| 3 | 2.0 | 0.0 | 4.0 | 7.0 |
| 4 | 3.0 | 3.0 | 4.0 | 7.0 |
| 5 | 3.0 | 3.0 | 4.0 | 7.0 |
| 6 | 3.0 | 4.0 | 4.0 | 7.0 |
| 7 | 3.0 | 4.0 | 4.0 | 7.0 |
| 8 | 3.0 | 4.0 | 4.0 | 7.0 |
| 9 | 3.0 | 4.0 | 4.0 | 7.0 |
| 10 | 3.0 | 4.0 | 4.0 | 0.0 |
| 11 | 0.0 | 3.0 | 0.0 | 0.0 |

Figure 2. Water release trajectory in each dam

There are only two inflows: 2 units to dam 1; 3 units to dam 2.

$$I_1 = 2, I_2 = 3 \quad (7)$$

Wardlaw and Sharif (1999) tackled this dam scheduling problem using an enhanced GA model (Population Size=100; Crossover Rate=0.70; Mutation Rate = 0.02; Number of Generations = 500; Number of Function Evaluations = 35,000; Binary, Gray, & Real-Value Representations; Tournament Selection; One-Point, Two-Point, & Uniform Crossovers; and Uniform and Modified Uniform Mutations). The GA model found a best near-optimal solution of 400.5, which is 99.8% of global optimum (401.3).

The HS model was applied to the same problem with the following algorithm parameters: HMS = 30; HMCR = 0.95; PAR = 0.05; and MaxImp = 35,000. The HS model could find five different global optimal solutions (HS1 ~ HS5) with identical cost of 401.3. Table 1 shows one example out of five optimal water release schedules.

Figure 2 shows corresponding release trajectories in all dams.

When the HS model was further tested with different algorithm parameter values, it found a better solution than that (400.5) of the GA model seven cases out of eight ones.

FUTURE TRENDS

From the success in this study, the future HS model should consider more complex dam scheduling problems with various real-world situations.

Also, algorithm parameter guidelines obtained from considerable experiments on the values will be helpful to engineers in practice because meta-heuristic algorithms, including HS and GA, require lots of trials to obtain best algorithm parameters.

CONCLUSION

Music-inspired algorithm, HS, was successfully applied to the optimal scheduling problem of the multiple dam system, outperforming the results of GA. While the GA model obtained near-optimal solutions, the HS

model found five different global optima under the same number of function evaluations.

Moreover, the HS model did not perform sensitivity analysis of algorithm parameters while the GA model tested many parameter values and different operation schemes. This could reduce time and trouble in choosing parameter values in HS.

KEY TERMS

Evolutionary Computation: Solution approach guided by biological evolution, which begins with potential solution models, then iteratively applies algorithms to find the fittest models from the set to serve as inputs to the next iteration, ultimately leading to a model that best represents the data.

Genetic Algorithm: Technique to search exact or approximate solutions of optimization or search problem by using evolution-inspired phenomena such as selection, crossover, and mutation. Genetic algorithm is classified as global search algorithm.

Harmony Search: Technique to search exact or approximate solutions of optimization or search problem by using music-inspired phenomenon (improvisation). Harmony search has three major operations such as random selection, memory consideration, and pitch adjustment. Harmony search is classified as global search algorithm.

Metaheuristics: Technique to find solutions by combining black-box procedures (heuristics). Here, 'meta' means 'beyond', and 'heuristic' means 'to find'.

Multiple Dam Scheduling: Process of developing individual dam schedule in multiple dam system. The schedule contains water release amount at each time period while satisfying release limit, storage limit, and continuity conditions.

Optimization: Process of seeking to optimize (minimize or maximize) an objective function while satisfying all problem constraints by choosing the values of continuous or discrete variables.

Soft Computing: Collection of computational techniques in computer science, especially in artificial intelligence, such as fuzzy logic, neural networks, chaos theory, and evolutionary algorithms.

Hierarchical Neuro–Fuzzy Systems Part I

INTRODUCTION

Neuro-fuzzy [Jang,1997][Abraham,2005] are **hybrid systems** that combine the learning capacity of **neural nets** [Haykin,1999] with the linguistic interpretation of **fuzzy inference systems** [Ross,2004]. These systems have been evaluated quite intensively in machine learning tasks. This is mainly due to a number of factors: the applicability of learning algorithms developed for **neural nets**; the possibility of promoting implicit and explicit knowledge integration; and the possibility of extracting knowledge in the form of fuzzy rules. Most of the well known **neuro-fuzzy systems**, however, present limitations regarding the number of inputs allowed or the limited (or nonexistent) form to create their own structure and rules [Nauck,1997][Nauck,1998][Vuorimaa,1994][Zhang,1995].

This paper describes a new class of **neuro-fuzzy models**, called Hierarchical Neuro-Fuzzy BSP Systems (HNFB). These models employ the BSP partitioning (**Binary Space Partitioning**) of the input space [Chrysanthou,1996] and have been developed to bypass traditional drawbacks of **neuro-fuzzy systems**. This paper introduces the HNFB models based on **supervised learning algorithm**. These models were evaluated in many benchmark applications related to **classification** and **time-series forecasting**. A second paper, entitled *Hierarchical Neuro-Fuzzy Systems Part II*, focuses on **hierarchical neuro-fuzzy models** based on reinforcement learning algorithms.

BACKGROUND

Hybrid Intelligent Systems conceived by using techniques such as Fuzzy Logic and Neural Networks have been applied in areas where traditional approaches were unable to provide satisfactory solutions. Many researchers have attempted to integrate these two techniques by generating hybrid models that associate their advantages and minimize their limitations and deficiencies. With this objective, hybrid neuro-fuzzy systems [Jang,1997][Abraham,2005] have been created.

Traditional neuro-fuzzy models, such as ANFIS [Jang,1997], NEFCLASS [Nauck,1997] and FSOM [Vuorimaa,1994], have a limited capacity for creating their own structure and rules [Souza,2002a]. Additionally, most of these models employ grid partition of the input space, which, due to the rule explosion problem, are more adequate for applications with a smaller number of inputs. When a greater number of input variables are necessary, the system's performance deteriorates.

Thus, *Hierarchical Neuro-Fuzzy Systems* have been devised to overcome these basic limitations. Different models of this class of **neuro-fuzzy systems** have been developed, based on **supervised technique**.

HIERARCHICAL NEURO-FUZZY SYSTEMS

This section presents the new class of **neuro-fuzzy systems** that are based on hierarchical partitioning.

Two sub-sets of **hierarchical neuro-fuzzy systems** (HNF) have been developed, according to the learning process used: **supervised learning models** (HNFB [Souza,2002b][Velasco,2004], HNFB⁻¹ [Gonçalves,2006], HNFB-Mamdani [Bezerra,2005]); and reinforcement learning models (RL-HNFB [Figueiredo,2005a], RL-HNFB [Figueiredo,2005b]). The focus of this paper is on the first sub-set of models, which are described in the following sections.

HIERACHICAL NEURO-FUZZY BSP MODEL

Basic Neuro-Fuzzy BSP Cell

An HNFB cell is a neuro-fuzzy mini-system that performs fuzzy **binary partitioning** of the input space. The HNFB cell generates a crisp output after a defuzzification process.

Figure 1(a) illustrates the cell's functionality, where 'x' represents the input variable; $\rho(x)$ and $\mu(x)$ are the membership functions *low* and *high*, respectively, which generate the antecedents of the two fuzzy rules; and y is the crisp output. The linguistic interpretation of the mapping implemented by the HNFB cell is given by the following rules:

- If $x \in \rho$ then $y = d_1$
- If $x \in \mu$ then $y = d_2$.

Each rule corresponds to one of the two partitions generated by BSP. Each partition can in turn be subdivided into two parts by means of another HNFB cell.

The profiles of membership functions $\rho(x)$ and $\mu(x)$ are complementary logistic functions.

The output y of an HNFB cell (defuzzification process) is given by the weighted average. Due to the fact that the membership function $\rho(x)$ is the complement to 1 of the membership function $\mu(x)$, the following equation applies:

$$y = \rho(x) * d_1 + \mu(x) * d_2 \text{ or } y = \sum_{i=1}^2 \alpha_i d_i \quad (1)$$

where α_i symbolizes the firing level of the rule in partition i and are given by: $\alpha_1 = \rho(x)$; $\alpha_2 = \mu(x)$. Each d_i corresponds to one of the three possible consequents below:

- A singleton: The case where $d_i = \text{constant}$.
- A linear combination of the inputs:

$$d_i = \sum_{k=1}^n w_k x_k + w_0$$

where: x_k is the system's k-th input; the w_k represent the weight associated with the input x_k ; 'n' is equal to the total number of inputs; and w_0 corresponds to a constant value.

- The output of a stage of a previous level: The case where $d_i = y_j$, where y_j represents the output of a generic cell 'j', whose value is also calculated by eq. (1).

HNFB Architecture

An HNFB model may be described as a system that is made up of interconnections of HNFB cells. Figure 1(b) illustrates an HNFB system along with the respective partitioning of the input space. In this system, the initial partitions 1 and 2 ('BSP0' cell) have been subdivided; hence, the consequents of its rules are the outputs of BSP1 and BSP2, respectively. In turn, these subsystems have, as consequents, values d_{11} , y_{12} , d_{21} and d_{22} , respectively. Consequent y_{12} is the output of the 'BSP12' cell. The output of the system in figure 1(b) is given by equation (2).

$$y = \alpha_1 (\alpha_{11} d_{11} + \alpha_{12} (\alpha_{121} d_{121} + \alpha_{122} d_{122})) + \alpha_2 (\alpha_{21} d_{21} + \alpha_{22} d_{22}) \quad (2)$$

It must be stressed that, although each BSP cell divides the input space only in two fuzzy set (*low* and *high*), the complete HNFB architecture divides the universe of discourse of each variable in as many partitions as necessary. The number of partitions is determined during the learning process. In Figure 1(c), for instance, the upper left part of the input space (partition 12 in gray) has been further subdivided by the horizontal variable x_j , resulting in three fuzzy sets for the complete universe of discourse of this specific variable.

Learning Algorithm

The HNFB system has a training algorithm based on the gradient descent method for learning the structure

Figure 1. (a) Interior of Neuro-Fuzzy BSP cell. (b) Example of HNFB system. (c) Input space Partitioning of the HNFB system

of the model and, consequently, linguistic rules. The parameters that define the profiles of the membership functions of the antecedents and consequents are regarded as fuzzy weights of the **neuro-fuzzy system**.

In order to prevent the structure from growing indefinitely, a non-dimensional parameter, named decomposition rate (δ), was created. More details of this algorithm may be found in [Souza,2002b][Gonçalves,2006].

The results obtained in **classification** and **time series forecasting** problems are presented in the Case Studies section.

HIERARCHICAL NEURO-FUZZY BPS FOR CLASSIFICATION

The original HNFB provides very good results for function approximation and **time series forecasting**. However, it is not ideal for **pattern classification** applications, since it has only one output and makes use of the **Takagi-Sugeno inference method** [Takagi,1985], which reduces the rule base interpretability.

Therefore, a new **hierarchical neuro-fuzzy BSP model** dedicated to **pattern classification** and **rule extraction**, called the Inverted HNFB or HNFB⁻¹, has been developed, which is able to extract classification rules such as: *If x is A and y is B then input-pattern belongs to class Z* . This new **hierarchical neuro-fuzzy model** is denominated *inverted* because it applies the learning process of the original HNFB to generate the model's structure. After this first learning phase, the

structure is inverted and the architecture of the HNFB⁻¹ model is obtained. The basic cell of this new inverted structure is described below.

Basic Inverted-HNFB Cell

Similarly to the original HNFB model, a basic Inverted-HNFB cell is a neuro-fuzzy mini-system that performs fuzzy **binary partitioning** in a particular space according to the same membership functions ρ and μ . However, after a defuzzification process, the Inverted-HNFB cell generates two crisp outputs instead of one. Fig. 2(a) illustrates the interior of the Inverted-HNFB cell.

By considering that membership functions are complementary, the outputs of an HNFB⁻¹ cell are given: $y_1 = \beta * \rho(x)$ and $y_2 = \beta * \mu(x)$, where β corresponds to one of the two possible cases below:

- β =the input of the first cell: so $\beta = 1$.
- β =is the output of a cell of a previous level: so $\beta = y_j$, where y_j represents one of the two outputs of a generic ' j ' cell.

Inverted-HNFB Architecture

Fig. 2(b) presents an example of the original HNFB architecture obtained during the training phase of a database containing three distinct classes, while Fig. 2(c) shows how the HNFB⁻¹ model is obtained, after the inversion process.

In the HNFB⁻¹ architecture shown in Fig. 2(c), it may be observed that the classification system has several outputs (y_1 to y_5), one for each existing leaf in the original HNFB architecture. The outputs of the leaf cells are calculated by means of the following equations (using complementary membership functions):

$$y_1 = \rho_0 \cdot \rho_1 \quad (3)$$

$$y_2 = \rho_0 \cdot \mu_1 \cdot \rho_{12} \quad (4)$$

$$y_3 = \rho_0 \cdot \mu_1 \cdot \mu_{12} \quad (5)$$

$$y_4 = \rho_1 \cdot \mu_1 \cdot \rho_{12} \quad (6)$$

$$y_5 = \mu_0 \cdot \mu_2 \quad (7)$$

where ρ_i and μ_i are the membership functions for the BSP_i.

HNFB⁻¹ System Outputs

After the inversion has been performed, the outputs are connected to T-conorm cells (OR operator) that define the classes (see Fig. 2(d)). The initial procedure for linking the leaf cells with all T-conorm neurons consists of connecting all leaf cells with all T-conorm neurons. Once these connections have been made, it is necessary to establish their weights. For the purpose of assigning

Figure 2. (a) HNFB⁻¹ basic cell. (b) Original HNFB architecture. (c) Inversion of the architecture shown in Fig. 2(b). (d) Connection of the inverted architecture to T-conorm cells

these weights, a learning method based on the Least Mean Squares [Haykin 1999] has been employed.

After the weights have been determined, the T-conorm operation (Limited Sum T-conorm operator [Ross,2004]) is used for processing the output of the neuron. The final output of the HNFB⁻¹ system is specified by the highest output obtained among all the T-conorm neurons, determining the class to which the input pattern belongs.

Results obtained with the HNFB⁻¹ model, in different benchmark **classification** problems, are presented in Case Studies section.

HIERARCHICAL NEURO-FUZZY BPS MAMDANI

The Hierarchical Neuro-Fuzzy BSP Mamdani (HNFB-Mamdani), as HNFB⁻¹, was also developed to enhance the interpretability of the **hierarchical neuro-fuzzy systems**. However, since the HNFB⁻¹ is dedicated to **classification** problems, a more general model was devised. The HNFB-Mamdani employs **Mamdani inference method** [Jang,1997] in the rules' consequents, and can be applied in control systems, **pattern classification**, **forecasting**, and **rule extraction**.

HNFB-Mamdani Architecture

The HNFB-Mamdani architecture is formed by the interconnection of HNFB⁻¹ cells in a binary tree structure and is divided into three basic modules: input partitioning structure; weighted connection from the binary structure leaf cells (d_i) to the T-conorm neurons (T_i); and the defuzzification process.

The first two modules are identical to the HNFB⁻¹ architecture, except that each T-conorm neuron is associated with a fuzzy set M of the consequent. All leaf cells are connected to all T-conorm neurons. To each connection there is a weight associated, whose value is also established by the Least Mean Squares algorithm.

The consequent of a fuzzy rule in the HNFB-Mamdani model is a fuzzy set represented by a triangular membership function. The total number of fuzzy sets associated with the output variable is specified by the user.

Defuzzification Method

The defuzzification process selected for the HNFB-Mamdani model is the weighted average of the maximum values. Figure 3 illustrates the defuzzification process for a model with three output fuzzy sets.

Figure 3. Defuzzification process

The output y is then calculated by Eq. (8).

$$y_j = \frac{\sum_{i=1}^n \alpha_i^j * C_i}{\sum_{i=1}^n \alpha_i^j} \quad (8)$$

where:

- y_j : output of the HNFB-Mamdani for input pattern j ;
- α_i^j : output value of the i -th T-conorm neuron (T_i) for input pattern j ;
- C_i : value in the universe of discourse of the output variable where the M_i fuzzy set presents the maximum value;
- $*$: product operator.
- n : total number of fuzzy sets associated with the output variable.

CASE STUDIES

In order to evaluate the performance of supervised HNFB models, two benchmark classification databases and six load time series from utilities of the Brazilian electrical energy sector were selected.

Pattern Classification

Pattern classification aims to determine to which group of a pre-determined set an input pattern belong to. Two benchmark applications were selected among those most frequently employed in the area of machine learning. The results obtained with the proposed HNFB models were compared to the ones described in [Gonçalves,2006]. In order to generate the training and test sets, the total set of patterns was randomly divided into two equal parts. Each of these two sets was alternately used either as a training or as a test set. Table 1 below summarizes the average classification performance obtained with both test sets. The performance of the HNFB models is better than the other models, except for the HNFB-Mamdani case. Since HNFB-Mamdani is a general-purpose model, it tends to provide inferior results when compared to application-specific models, such as Inverted-HNFB and HNFB-Class. On the other hand, HNFB and HNFQ [Souza,2002a] are also general-purpose models but still

provide a superior performance than HNFB-Mamdani. This is due to the **Takagi-Sugeno inference method** used by those models, which is usually more accurate than the **Mamdani inference method** [Bezerra,2005]. The disadvantage of the **Takagi-Sugeno method** is its reduced interpretability.

Electric Load Forecasting

This experiment made use of data related to the monthly electric load of 6 utilities of the Brazilian electrical energy sector.

The results obtained with the HNFB models were compared with *Backpropagation* algorithm, statistical techniques, such as the *Holt-Winters* and *Box & Jenkins*,

Table 1. Comparison of the average classification performance

| | Iris | Wine |
|---------------|---------|---------|
| NN | - | 95.20 % |
| KNN | - | 96.70% |
| FSS | - | 92.80 % |
| BSS | - | 94.80 % |

and with Bayesian **Neural Nets** (BNN) [Bishop,1995], trained by Gaussian approximation and by the MCMC method. Table 2 below presents the performance results in terms of the “*Mean Absolute Percentage Error*”.

It can be observed that the general performance of HNFB models is usually superior to the results provided by statistical methods. The results obtained with BNNs are generally better than with HNFB models. However, according to [Tito,1999], the training time with BNN was about 8 hours. This was a much longer period than the time required by the HNFB models to perform the same task, which was of the order of tens to hundreds of seconds, on similar equipment. Additionally, the data used in the HNFB models were not treated in terms of their seasonal aspects, nor were they made stationary as was the case of the BNN tested in [Tito,1999].

FUTURE TRENDS

As can be seen from the results presented, HNFB models provide very good performance in different applications. To improve the performance of the HNFB-Mamdani model, which provided the worst results among the supervised HNFB models, the model is being extended to allow the use of different types of output fuzzy sets (such as Gaussian, trapezoidal, etc.) and by adding an algorithm to optimize the total number of output fuzzy sets.

CONCLUSION

The objective of this article was to introduce a new class of **neuro-fuzzy models** which aims to improve the weak points of conventional **neuro-fuzzy systems**. The results obtained by the HNFB models showed that they yield a good performance as classifiers of database patterns or as time series forecasters. These models are able to create their own structure and allow the extraction of knowledge in the form of linguistic fuzzy rules.

KEY TERMS

Artificial Neural Networks: Composed of several units called neurons, connected through synaptic weights, which are iteratively adapted to achieve the desired response. Each neuron performs a weighted sum of its inputs, which is then passed through a nonlinear function that yields the output signal. ANNs have the ability to perform a non-linear mapping between their inputs and outputs, which is learned by a training algorithm.

Bayesian Neural Networks: Multi-layer neural networks that use training algorithms based on statistical Bayesian inference. BNNs offer a number of important advantages over the standard Backpropagation learning algorithm including: confidence intervals can be assigned to the predictions generated by a network; they allow the values of regularization coefficients to be selected using only training data; similarly, they allow different models to be compared using only the training data dealing with the issue of model complexity without the need to use cross validation.

Binary Space Partitioning: The space is successively divided in two regions, in a recursive way. This partitioning can be represented by a binary tree that illustrates the successive n-dimensional space subdivisions in two convex subspaces. This process results in two new subspaces that can be later partitioned by the same method.

Fuzzy Logic: Can be used to translate, in mathematical terms, the imprecise information expressed by a set of linguistic IF-THEN rules. Fuzzy Logic studies the formal principles of approximate reasoning and is based on Fuzzy Set Theory. It deals with intrinsic imprecision, associated with the description of the properties of a phenomenon, and not with the imprecision associated with the measurement of the phenomenon itself. While classical logic is of a bivalent nature (true or false), fuzzy logic admits multivalence.

Machine Learning: Concerned with the design and development of algorithms and techniques that allow computers to “learn”. The major focus of machine learning research is to automatically extract useful information from historical data, by computational and statistical methods.

Pattern Recognition: A sub-topic of machine learning, which aims to classify input patterns into a specific class of pre-defined groups. The classification is usually based on the availability of a set of patterns that have already been classified. Therefore, the resulting learning strategy is based on supervised learning.

Supervised Learning: A machine learning technique for creating a function from training data, which consist of pairs of input patterns as well as the desired outputs. Therefore, the learning process depends on the existence of a “teacher” that provides, to each input pattern, the real output value. The output of the function can be a continuous value (called regression), or a class label of the input object (called classification).

Hierarchical Neuro-Fuzzy Systems Part II

INTRODUCTION

This paper describes a new class of neuro-fuzzy models, called Reinforcement Learning Hierarchical Neuro-Fuzzy Systems (RL-HNF). These models employ the BSP (**Binary Space Partitioning**) and Polintree partitioning of the input space [Chrysanthou, 1992] and have been developed in order to bypass traditional drawbacks of **neuro-fuzzy systems**: the reduced number of allowed inputs and the poor capacity to create their own structure and rules (ANFIS [Jang, 1997], NEFCLASS [Kruse, 1995] and FSOM [Vuorimaa, 1994]).

These new models, named Reinforcement Learning Hierarchical Neuro-Fuzzy BSP (RL-HNFB) and Reinforcement Learning Hierarchical Neuro-Fuzzy Polintree (RL-HNFP), descend from the original HNFB that uses **Binary Space Partitioning** (see Hierarchical Neuro-Fuzzy Systems Part I). By using hierarchical partitioning, together with the **Reinforcement Learning** (RL) methodology, a new class of **Neuro-Fuzzy Systems** (SNF) was obtained, which executes, in addition to automatically learning its structure, the autonomous learning of the actions to be taken by an agent, dismissing a priori information (number of rules, fuzzy rules and sets) relative to the learning process. These characteristics represent an important differential when compared with existing intelligent **agents** learning systems, because in applications involving continuous environments and/or environments considered to be highly dimensional, the use of traditional **Reinforcement Learning** methods based on lookup tables (a table that stores value functions for a small or discrete state space) is no longer possible, since the state space becomes too large.

This second part of **hierarchical neuro-fuzzy systems** focus on the use of **reinforcement learning** process. The first part presented HNFB models based on supervised learning methods. The RL-HNFB and RL-HNFP models were evaluated in a benchmark **control application** and a simulated Khepera robot environment with multiple obstacles.

BACKGROUND

The model described in this paper was developed based on an analysis of the limitations in existing models and of the desirable characteristics for RL-based learning systems, particularly in applications involving continuous and/or high dimensional environments [Jouffe, 1998][Sutton, 1998][Barto, 2003][Sato, 2006]. Thus, the *Reinforcement Learning Hierarchical Neuro-Fuzzy Systems* have been devised to overcome these basic limitations. Two different models of this class of **neuro-fuzzy systems** have been developed, based on **reinforcement learning** techniques.

HIERARCHICAL NEURO-FUZZY SYSTEMS

This section presents the new class of **neuro-fuzzy systems** that are based on hierarchical partitioning. As mentioned in the first part, two sub-sets of **hierarchical neuro-fuzzy systems** have been developed, according to the learning process used: supervised learning models (HNFB [Souza, 2002][Velasco, 2004], HNFB⁻¹ [Gonçalves, 2006], HNFB-Mamdani [Bezerra, 2005]);

and **reinforcement learning** models (RL-HNFB [Figueiredo,2005a], RL-HNFP [Figueiredo,2005b]). The focus of this article is on the second sub-set of models. These models are described in the following sections.

REINFORCEMENT LEARNING HIERARCHICAL NEURO-FUZZY MODELS

The RL-HNFB and RL-HNFP models are composed of one or various standard cells, called RL-neuro-fuzzy-BSP (RL-NFB) and RL-neuro-fuzzy-Politree (RLNFP), respectively. The following sub-sections describe the basic cells, the hierarchical structures and the learning algorithm.

Reinforcement Learning Neuro-Fuzzy BSP and Politree Cells

An RL-NFB cell is a mini-neuro-fuzzy system that performs **binary partitioning** of a given space in accordance with ρ and μ membership functions. In the same way, an RL-NFP cell is a mini-neuro-fuzzy system that performs 2^n partitioning of a given input space, also using complementary membership functions in each input dimension. The RL-NFB and RL-NFP cells generate a precise (crisp) output after the defuzzification process [Figueiredo,2005a][Figueiredo,2005b].

The RL-NFB cell has only one input (x) associated with it. The RL-NFP cell receives all the inputs that are being considered in the problem. For illustration purpose, figure 1(a) depicts a cell with two inputs – x_1 and x_2 - (**Quadtree partitioning**), providing a simpler representation than the n -dimensional form of Politree. In figure 1(a) each partitioning is generated by the combination of two membership functions - ρ (*low*) and μ (*high*) of each input variable.

The consequents of the cell's poli-partitions may be of the *singleton* type or the output of a stage of a previous level. Although the *singleton* consequent is simple, this consequent is not previously known because each *singleton* consequent is associated with an action that has not been defined a priori. Each poli-partition has a set of possible actions (a_1, a_2, \dots, a_n), as shown in figure 1(a), and each action is associated with a Q -value function. The Q -value is defined as being the sum of the expected values of the rewards obtained

by the execution of action a in state s , in accordance with a policy π . For further details about RL theory, see [Sutton,1998].

The linguistic interpretation of the mapping implemented by the RL-NFP cell depicted in Figure 1(a) is given by the following set of rules:

rule₁: If $x_1 \in \rho_1$ and $x_2 \in \rho_2$ then $y = a_i$
 rule₂: If $x_1 \in \rho_1$ and $x_2 \in \mu_2$ then $y = a_j$
 rule₃: If $x_1 \in \mu_1$ and $x_2 \in \rho_2$ then $y = a_p$
 rule₄: If $x_1 \in \mu_1$ and $x_2 \in \mu_2$ then $y = a_q$

where consequent a_i corresponds to one of the two possible consequents below:

a singleton (fuzzy singleton consequent, or zero-order Sugeno): the case where $a_i = \text{constant}$;
the output of a stage of a previous level: the case where $a_i = y_m$, where y_m represents the output of a generic cell 'm'.

RL-HNFB and RL-HNFP Architectures

RL-HNFB and RL-HNFP models can be created based on the interconnection of the basic cells. The cells form a hierarchical structure that results in the rules that compose the **agent's** reasoning.

In the example of an architecture presented in figure 1(b), the poli-partitions 1, 3, 4, ..., $m-1$ have not been subdivided, having as consequents of its rules the values $a_1, a_3, a_4, \dots, a_{m-1}$, respectively. On the other hand, poli-partitions 2 and m have been subdivided; so the consequents of its rules are the outputs (y_2 and y_m) of subsystems 2 and m , respectively. On its turn, these subsystems have, as consequent, the values $a_{21}, a_{22}, \dots, a_{2m}$, and $a_{m1}, a_{m2}, \dots, a_{mm}$, respectively. Each ' a_i ' corresponds to a consequent of zero-order Sugeno (singleton), representing the action that will be identified (between the possible actions), through **reinforcement learning**, as being the most favorable for a certain state of the environment. It must be stressed that the definition of which partition must be subdivided or not is defined automatically by the learning algorithm.

The output of the system depicted in figure 1(b) (defuzzification) is given by equation (1). In these equations, α_i corresponds to the firing level of partition i and a_i is the singleton consequent of the rule associated with partition i .

Figure 1. (a) RL-NHP cell; (b) RL-HNFP architecture

$$y = \alpha_1 . a_1 + \alpha_2 \sum_{i=1}^{2^n} \alpha_{2i} . a_{2i} + \alpha_3 . a_3 + \alpha_4 . a_4 + \dots + \alpha_m \sum_{i=1}^{2^n} \alpha_{mi} . a_{mi} \quad (1)$$

RL-HNFB and RL-HNFP Learning Algorithm

The learning process starts with the definition of the relevant inputs for the system/environment where the **agent** is and the sets of actions it may use in order to achieve its objectives. The **agent** must run many cycles to ensure learning in the system/environment where it is. A cycle is defined as the number of steps the agent takes in the environment, which extends from the point he is initiated to the target point.

The RL-HNFB and RL-HNFP models employ the same learning algorithm. Each partition chooses an action from its set of actions; the resultant action is calculated by the defuzzification process and represents the action that will be executed by the **agents'** actuators. After the resultant action is carried out, the environment is read once again. This reading enables calculation of the environment reinforcement value that will be used to evaluate the action taken by the **agent**. The reinforcement is calculated for each partition of all active cells, by means of its participation in the resulting action. Thus, the environment reinforcement calculated by the evaluation function is backpropagated from the root-cell to the leaf-cells. Next, the Q-values associated to the actions that have contributed to the resulting action are updated, based on the SARSA

algorithm [Sutton,1998]. More details can be found in [Figueiredo,2005b].

The RL_HNFB and RL_HNFP models have been evaluated in different **control applications**. Two of these **control application** are presented in the next section.

CASE STUDIES

Cart-Centering

The *cart-centering problem* [Koza,1992] is generally used as a benchmark of the area of evolutionary programming, where the force that is applied to the car is of the “bang bang” type [Koza,1992]. This problem was used mainly for the purpose of evaluating how well the RL-HNFB and RL-HNFP models would adapt to changes in the input variable domain without having to undergo a new training phase.

The problem consists of parking, in the centre of a one-dimensional environment, a car with mass m that moves along this environment due to an applied force F . The input variables are the position (x) of the car, and its velocity (v). The objective is to park the car in position $x = 0$ with velocity $v = 0$. The equations of motion are (where the τ parameter represents the time unit):

$$x_{t+\tau} = x_t + \tau . v_t \quad v_{t+\tau} = v_t + \tau . F_t / m \quad (2)$$

The global reinforcement is calculated by equation (3) below:

If $(x > 0 \text{ and } v < 0)$ or $(x < 0 \text{ and } v > 0)$

$$R_{global} = k_1 e^{-(\text{distance_objective})} + k_2 e^{(\text{velocity})} \quad (3)$$

Else $R_{global} = 0$

The evaluation function increases as the car gets closer to the centre of the environment with velocity zero. The k_1 and k_2 coefficients are constants greater than 1 used for adapting the reinforcement values to the model's structure. The values used for time unit and mass were $\tau=0.02$ and $m=2.0$.

The stopping criterion is achieved when the difference between the velocity and the position value in relation to the objective ($x=0$ and $v=0$) is smaller than 5% of the universe of discourse of the position and velocity inputs.

Table 1 shows the average of the results obtained in 5 experiments for each configuration. The columns position and velocity limits refer to the limits imposed to the (position and velocity) state variables during learning and testing. The actions used in these experiments are: $F1 = \{-150, -75, -50, -30, -20, -10, -5, 0, 5, 10, 20, 30, 50, 75, 150\}$. The size of the structure column shows the average of the number of cells at the end of each experiment and the last column shows the average steps during the learning phase. The number of cycles was

Table 1. Results of the RL-HNFB and RL-HNFP models applied to the cart-centering problem

| No. | Position Limits | Velocity Limits | Size of the Structure | Average steps learning phase |
|----------------------|-----------------|-----------------|-----------------------|------------------------------|
| RL-HNFB ₁ | 10 | 10 | 195 cells | 424 |
| RL-HNFB ₂ | 3 | 3 | 340 cells | 166 |
| RL-HNFP ₁ | 10 | 10 | 140 cells | 221 |
| RL-HNFP ₂ | 3 | 3 | 251 cells | 145 |

Table 2. Testing results of the proposed models applied to the cart-centering problem

| Configuration | Initial Position | | |
|----------------------|-------------------------|-----|-----|
| | 3 | 2 | 1 |
| | Average number of steps | | |
| RL-HNFB ₁ | 387 | 198 | 141 |
| RL-HNFB ₂ | 122 | 80 | 110 |
| RL-NFHP ₁ | 190 | 166 | 99 |
| RL-NFHP ₂ | 96 | 124 | 68 |

fixed at 1000. At each cycle, the car's starting points were $x=-3$ or $x=3$.

As can be observed from Table 1, the RL-HNFP structure is smaller because each cell receives both input variables, while in the case of the RL-HNFB model, a different input variable is applied at each level of the BSP tree.

Table 2 presents the results obtained for one of the 5 experiments carried out at each configuration shown in Table 1 when the car starts out at points $(-2, -1, 1, 2)$ which were not used in the learning phase.

In the first configuration of each model, the results show that the broader the position and velocity limits are (in this case equal to $|10|$), the more difficult it is to learn. In these cases a small oscillation occurs around the central point. What actually happens is that the final velocity is very small but, after some time, it tends to move the car out of the convergence area, resulting in a peak of velocity in the opposite direction to correct the car's position. In the second configurations, fewer oscillations occur because the position and velocity limits were lowered to $|3|$.

Khepera Robot

The RL-HNFP model was also tested with a Khepera robot simulator [Figueiredo,2005b]. The model was tested in a squared environment where the **agent** moved from one of the corners to reach the diametric opposite corner. Nevertheless, he could not pass through the ambient center because of an obstacle.

The Khepera robot acquires ambient signs using 8 sensors grouped into 4: one ahead, one in each side and

one behind. Its actions are executed via 2 independent motors with power varying between -20 and 20 , one in the right side and the other in the left side.

The RL-HNFP model was trained in one environment with a big central square obstacle, called environment I (Figure 2). It was tested in two environments: the same environment I (with a big central square obstacle) but with different initial positions; and another environment with four additional obstacles. These new multi-obstacle environment, (environment II), comprises: big central, small top-left, bottom-right and left obstacles (see Figure 3).

In all experiments using both environments the robot's objective was to reach position $(5, 5)$. In figures 2 and 3 the white circles indicate the initial positions of the robot while the gray circles show their final positions.

Figure 2. Tests in environments I

Figure 3. Tests in environments II

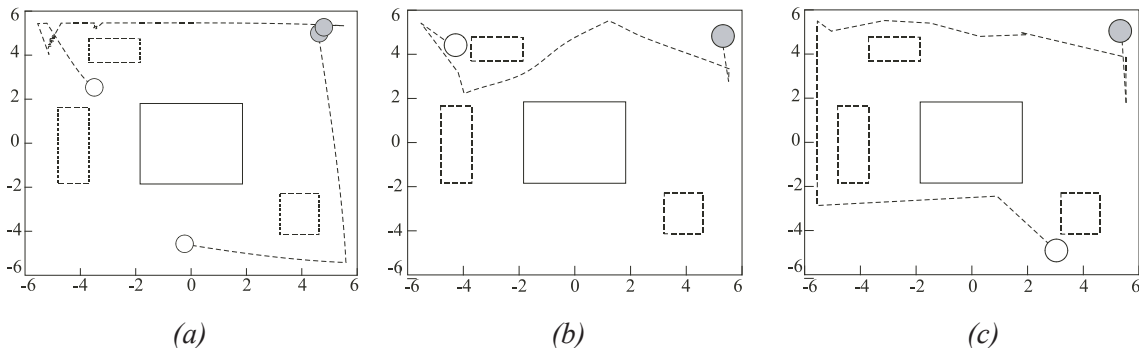

Figure 2 shows the experiments on the environment I. The results refer to tests executed with a structure trained from a variety of positions different from the ones used on the tests, demonstrating that the acquired knowledge was generalized and that the obtained results conform to the expectative.

Figures 3(a), 3(b) and 3(c) show experiments in environment II. The results described in these figures refer to tests executed in the environment II with the knowledge acquired in the environment I. Note that the three additional obstacles do not affect the results in these experiments.

As demonstrated from these figures, the results indicate the good performance of the model. This is even more important when one considers that the number of learning cycles was very small (only 400 cycles). The result presented in figure 3(c) stands out this fact. In this case, the **agent** does not take the shortest path to the goal point. On the contrary, it turns round the environment in some points until take the way to the goal point. To improve the robot's performance, the model should be executed for at least 2000 cycles, as already demonstrated from previous cases using this application [Figueiredo,2005b].

FUTURE TRENDS

Regarding the Reinforcement Learning Hierarchical neuro-fuzzy models, some improvements are also under development. To improve their performance it is intended to execute tests with *Eligibility Traces* [Sutton,1998]. This is a method that does not update only the current state function value, but also the function value of previous states inside a predefined limit.

Another proposal for improving model RL-NFHP is the use of the **WoLF** principle (Win or Learn Fast) [Bowling,2002] to modify the learning rate that adjusts the politics. The **WoLF** principle consists of learning quickly when it is losing and more slowly when it is winning. Also it is intended to evaluate these models using real robots.

The RL-HNFP model is also being modified to be used in a cooperative multi-agents environment. In this environment the learning process is accomplished by sharing the acquired knowledge among the existent agents.

CONCLUSION

The objective of this paper was to introduce a new class of **neuro-fuzzy models** which aims to improve the weak points of conventional **neuro-fuzzy systems**. The models RL-NFHB and RL-HNFP belong to this new class of **neuro-fuzzy systems** called Hierarchical Neuro-Fuzzy System.

The RL-NFHB and RL-HNFP models were able to create and expand the structure of rules without any prior knowledge (fuzzy rules or sets); extract knowledge from the agent's direct interaction with large and/or continuous environments (through **reinforcement learning**), in order to learn which actions are to be carried out; and produce interpretable fuzzy rules, which compose the agent's intelligence to achieve his goal(s). The agent was able to generalize its actions, showing adequate behaviour when the agent was in states whose actions had not been specifically learned. This capacity increases the agent's autonomy.

KEY TERMS

Binary Space Partitioning: In this type of partitioning, the space is successively divided in two regions, in a recursive way. This partitioning can be represented by a binary tree that illustrates the successive n-dimensional space sub-divisions in two convex subspaces. The construction of this partitioning tree (BSP tree) is a process in which a subspace is divided by a hyper-plan parallel to the co-ordinates axes. This process results in two new subspaces that can be later partitioned by the same method.

Fuzzy Inference Systems: Fuzzy inference is the process of mapping from a given input to an output using fuzzy logic. The mapping then provides a basis from which decisions can be made, or patterns discerned. Fuzzy inference systems have been successfully applied in fields such as automatic control, data classification, decision analysis.

Machine Learning: Concerned with the design and development of algorithms and techniques that allow computers to “learn”. The major focus of machine learning research is to automatically extract useful information from historical data, by computational and statistical methods.

Politree Partitioning: The Politree partitioning was inspired by the quadtree structure, which has been widely used in the area of images manipulation and compression. In the politree partitioning the subdivision of the n-dimensional space is accomplished by $m=2^n$ subdivision. The Politree partitioning can be represented by a tree structure where each node is subdivided in m leafs (Politree partitioning).

Quadtree Partitioning: In this type of partitioning, the space is successively divided in four regions, in a recursive way. This partitioning can be represented

by a quaternary tree that illustrates the successive n-dimensional space sub-divisions in four convex subspaces. The construction of this partitioning tree (Quad tree) is a process in which a subspace is divided by a two hyper-plan parallel to the co-ordinates axes. This process results in four new subspaces that can be later partitioned by the same method. The limitation of the Quadtree partitioning (fixed or adaptive) is in the fact that it works only in two-dimensional spaces.

Reinforcement Learning: A sub-area of machine learning concerned with how an *agent* ought to take *actions* in an *environment* so as to maximize some notion of long-term *reward*. Reinforcement learning algorithms attempt to find a *policy* that maps *states* of

the world to the actions the agent ought to take in those states. Differently from supervised learning, in this case there is no target value for each input pattern, only a reward based on how good or bad was the action taken by the agent in the existant environment.

Sarsa: It is a variation of the Q-learning (Reinforcement Learning) algorithm based on model-free action policy estimation. SARSA admits that the actions are chosen randomly with a predefined probability.

WoLF: (“Win or Learn Fast”) is a method by [Bowling, 2002] for changing the learning rate to encourage convergence in a multi-agents reinforcement learning scenario.

Hierarchical Reinforcement Learning

Carlos Diuk

Rutgers University, USA

Michael Littman

Rutgers University, USA

INTRODUCTION

Reinforcement learning (RL) deals with the problem of an agent that has to learn how to behave to maximize its utility by its interactions with an environment (Sutton & Barto, 1998; Kaelbling, Littman & Moore, 1996). Reinforcement learning problems are usually formalized as Markov Decision Processes (MDP), which consist of a finite set of states and a finite number of possible actions that the agent can perform. At any given point in time, the agent is in a certain state and picks an action. It can then observe the new state this action leads to, and receives a reward signal. The goal of the agent is to maximize its long-term reward.

In this standard formalization, no particular structure or relationship between states is assumed. However, learning in environments with extremely large state spaces is infeasible without some form of generalization. Exploiting the underlying structure of a problem can effect generalization and has long been recognized as an important aspect in representing sequential decision tasks (Boutilier et al., 1999).

Hierarchical Reinforcement Learning is the subfield of RL that deals with the discovery and/or exploitation of this underlying structure. Two main ideas come into play in hierarchical RL. The first one is to break a task into a hierarchy of smaller subtasks, each of which can be learned faster and easier than the whole problem. Subtasks can also be performed multiple times in the course of achieving the larger task, reusing accumulated knowledge and skills. The second idea is to use state abstraction within subtasks: not every task needs to be concerned with every aspect of the state space, so some states can actually be *abstracted away* and treated as the same for the purpose of the given subtask.

BACKGROUND

In this section, we will introduce the MDP formalism, where most of the research in standard RL has been done. We will then mention the two main approaches used for learning MDPs: model-based and model-free RL. Finally, we will introduce two formalisms that extend MDPs and are widely used in the Hierarchical RL field: semi-Markov Decision Processes (SMDPs) and Factored MDPs.

Markov Decision Processes (MDPs)

A Markov Decision Process consists of:

- a set of states S
- a set of actions A
- a transition probability function: $Pr(s' | s, a)$, representing the probability of the environment transitioning to state s' when the agent performs action a from state s . It is sometimes notated $T(s, a, s')$.
- a reward function: $E[r | s, a]$, representing the expected immediate reward obtained by taking action a from state s .
- a discount factor $\gamma \in (0, 1]$, that downweights future rewards and whose precise role will be clearer in the following equations.

A *deterministic policy* $\pi: S \rightarrow A$ is a function that determines, for each state, what action to take. For any given policy π , we can define a *value function* V^π , representing the *expected infinite-horizon discounted return* to be obtained from following such a policy starting at state s :

$$V^\pi(s) = E[r_0 + \gamma r_1 + \gamma^2 r_2 + \gamma^3 r_3 + \dots].$$

Bellman (1957) provides a recursive way of determining the value function when the reward and transition probabilities of an MDP are known, called the *Bellman equation*:

$$V^\pi(s) = R(s, \pi(s)) + \gamma \sum_{s'} T(s, \pi(s), s') V^\pi(s'),$$

commonly rewritten as an *action-value function* or *Q-function*:

$$Q^\pi(s, a) = R(s, a) + \gamma \sum_{s'} T(s, a, s') V^\pi(s').$$

An *optimal policy* $\pi^*(s)$ is a policy that returns the action a that maximizes the value function:

$$\pi^*(s) = \operatorname{argmax}_a Q^*(s, a)$$

States can be represented as a set of *state variables* or *factors*, representing different features of the environment: $s = \langle f_1, f_2, f_3, \dots, f_n \rangle$.

Learning in Markov Decision Processes (MDPs)

The reinforcement-learning problem consists of determining or approximating an optimal policy through repeated interactions with the environment (*i.e.*, based on a sample of *experiences* of the form $\langle \text{state} - \text{action} - \text{next state} - \text{reward} \rangle$).

There are three main approaches to learning such an optimal or near-optimal policy:

- **Policy-search methods:** learn a policy directly via evaluation in the environment.
- **Model-free (or direct) methods:** learn the policy by directly approximating the Q function with updates from direct experience.
- **Model-based (or indirect) methods:** first learn the transition probability and reward functions, and use those to compute the Q function by means of, for example, the *Bellman equations*.

Model-free algorithms are sometimes referred to as the *Q-learning family* of algorithms. See Sutton (1988) or Watkins (1989) for the first best-known examples. It is known that model-free methods make inefficient use of experience, but they do not require expensive

computation to obtain the Q function and the corresponding optimal policy.

Model-based methods make more efficient use of experience, and thus require less data, but they involve an extra *planning* step to compute the value function, which can be computationally expensive. Some well-known algorithms can be found in the literature (Sutton, 1990; Moore & Atkeson, 1993; Kearns & Singh, 1998; and Brafman & Tennenholtz, 2002).

Algorithms for reinforcement learning in MDP environments suffers from what is known as the *curse of dimensionality*: an exponential explosion in the total number of states as a function of the number of *state variables*. To cope with this problem, *hierarchical methods* try to break down the intractable state space into smaller pieces, which can be learned independently and reused as needed. To achieve this goal, changes need to be introduced to the standard MDP formalism. In the introduction we mentioned the two main ideas behind hierarchical RL: task decomposition and state abstraction. Task decomposition implies that the agent will not only be performing single-step actions, but also full subtasks which can be extended in time. Semi-Markov Decision Processes (SMDPs) will let us represent these extended actions. State abstraction means that, in certain contexts, certain aspects of the state space will be ignored, and states will be grouped together. Factored-state representations is one way of dealing with this. The following section introduces these two common formalisms used in the HRL literature.

Beyond MDPs: SMDPs and Factored-State Representations

We'll consider the limitations of the standard MDP formalism by means of an illustrating example. Imagine an agent whose task is to exit a multi-storyed office building. The starting position of the agent is a certain office in a certain floor, and the goal is to reach the front door at ground level. To complete the task, the agent has to first exit the room, find its way through the hallways to the elevator, take the elevator to the ground floor, and finally find its way from the elevator to the exit. We would like to be able to reason in terms of subtasks (e.g., “*exit room*”, “*go to elevator*”, “*go to floor X*”, etc.), each of them of different durations and levels of abstraction, each encompassing a series of

lower-level or *primitive* actions. Each of these subtasks is also concerned with only certain aspects of the full state space: while the agent is inside the room, and the current task is to exit it, the floor the elevator is on, or whether the front door of the building is open or closed, is irrelevant. However, these features will become crucial later as the agent's subtask changes.

Under the MDP formalization, time is represented as a discrete step of unitary and constant duration. This formulation does not allow the representation of temporally extended actions of varying durations, amenable to represent the kind of higher-level actions identified in the example. The formalism of semi-Markov Decision Processes (SMDPs) enables this representation (Puterman, 1994). In SMDPs, the transition function is altered to represent the probability that action a from state s will lead to next state s' after t timesteps:

$$Pr(s', t | s, a)$$

The corresponding value function is now:

$$V^\pi(s) = R(s, \pi(s)) + \sum_{s' \in S} \gamma^t Pr(s', t | s, a) V^\pi(s')$$

SMDPs also enable the representation of continuous time. For dynamic programming algorithms for solving SMDPs, see Puterman (1994) and Mahadevan et al., (1997).

Factored-state MDPs deal with the fact that certain aspects of the state space are irrelevant for certain actions. In factored-state MDPs, state variables are decomposed into independently specified components, and transition probabilities are defined as a product of factor probabilities. A common way of representing independence relations between state variables is through *Dynamic Bayes Networks* (DBNs). As an example, imagine that the state is represented by four state variables: $s = \langle f_1, f_2, f_3, f_4 \rangle$, and we know that for action a the value of variable f_1 in the next state only depends on the prior values of f_1 and f_4 , f_2 depends on f_2 and f_3 , and the others only depend on their own prior value. This transition probability in a Factored MDP would be represented as:

$$Pr(s' | s, a) = Pr(f_1' | f_1, f_4, a) Pr(f_2' | f_2, f_3, a) Pr(f_3' | f_3, a) Pr(f_4' | f_4, a)$$

For learning algorithms in factored-state MDPs, see Kearns & Koller (1999) and Guestrin et al. (2002).

HIERARCHICAL REINFORCEMENT-LEARNING METHODS

Different approaches and goals can be identified within the hierarchical reinforcement-learning subfield. Some algorithms are concerned with learning a hierarchical view of either the environment or the task at hand, while others are just concerned with exploiting this knowledge when provided as input. Some techniques try to learn or exploit temporally extended actions, abstracting together a set of actions that lead to the completion of a subtask or subgoal. Other methods try to abstract together different states, treating them as if they were equal from the point of view of the learning problem.

We will briefly review a set of algorithms that use some combination of these approaches. We will also identify which of these methods are based on the model-free learning paradigm as opposed to those that try to construct a model of the environment.

Options: Learning Temporally Extended Actions in the SMDP Framework

Options make use of the SMDP framework to allow the agent to group together a series of actions (an option's policy) that lead to a certain state or set of states identified as subgoals. For each option, a set of valid start states is also identified, where the agent can decide whether to perform a single-step primitive action, or to make use of the option. We can think of options as pre-stored policies for performing abstract subtasks.

A learning algorithm for options is described by Sutton, Precup & Singh (1999) and belongs to the model-free Q-learning family. In its current formulation, the options framework allows for two-level hierarchies of tasks, although they could potentially be generalized to multiple levels. End states (*i.e.*, subgoals) are given as input to the algorithm. There is work devoted to discovering these subgoals and constructing useful options from them (Şimşek et al., 2005; and Jong & Stone, 2005).

While *options* have been shown to improve the learning time of model-free algorithms, it is not clear that there is an advantage in terms of learning time over model-based methods. As any model-free method, though, they do not suffer from the computational cost involved in the planning step. It is still an open question whether options can be generalized to multiple-level hierarchies, and most of the work is empirical, with no theoretical bounds.

MaxQ: Combining a Hierarchical Task Decomposition with State Abstraction

MaxQ is also a model-free algorithm in the Q-learning family. It receives as input a multi-level hierarchical task decomposition, which decomposes the full underlying MDP into an additive combination of smaller MDPs. Within each task, abstraction is used so that state variables that are irrelevant for the task are ignored (Dietterich, 2000).

The main drawback of *MaxQ* is that the hierarchy and abstraction have to be provided as input, and in its model-free form it misses opportunities for faster learning.

DSHP: Model-Based Hierarchical Decomposition for Efficient Learning and Planning

Deterministic Sample-Based Hierarchical Planning (DSHP) combines factored-state MDP representations, a *MaxQ* hierarchical task decomposition, and model-based learning to achieve provably efficient learning and planning in deterministic domains (Diuk, Strehl & Littman, 2006).

While, as a model-based algorithm, *DSHP* allows for faster learning and planning, it still suffers from the problem that the hierarchy and abstraction have to be provided as input.

HEXQ: Discovering Hierarchy

As opposed to *MaxQ*, *DSHP*, or other methods that receive the hierarchical task decomposition as input, *HEXQ* tries to automatically discover it. *HEXQ* analyses traces of experience and identifies regions of the MDP with repeated characteristics. It uses this experience to build temporal and state abstractions, constructing a

hierarchy of smaller interlinked MDPs. *HEXQ* is model-free and based on Q-learning (Hengst, 2002).

HEXQ shows a promising method for discovering abstractions and hierarchies, but still suffers from a lack of any theoretical bounds or proofs. All the work using *HEXQ* has been empirical, and its general power still remains an open question.

HAM-PHAM: Restricting the Class of Possible Policies

Hierarchies of Abstract Machines (HAMs) also make use of the SMDP formalism. The main idea is to restrict the class of possible policies by means of small nondeterministic finite-state machines, which constrain the sequences of actions that are allowed. Elements in *HAMs* can be thought of as small programs, which at certain points can decide to make calls to other lower-level programs (Parr & Russell, 1997; and Parr, 1998). See also *Programmable HAMs (PHAMs)*, an extension by Andre & Russell (2000).

HAM provides an interesting approach to make learning and planning easier, but has also only been shown to work better in certain empirical examples.

FUTURE TRENDS

We expect to see most of the new work in the field of Hierarchical Reinforcement Learning tackling two areas: hierarchy and abstraction discovery, and transfer learning. We believe the main open question is how structure can be learned from experience, and once learned be applied to tasks and problems different from the original one.

There is also promising but still little theoretical work currently being produced in the area, work that could prove the general power of different methods. Most of the work is empirical and only shown to work through experiments in small domains.

CONCLUSION

The goal of hierarchical reinforcement learning is to combat the “curse of dimensionality”, the main obstacle in achieving scalable RL that can be applied to real-life problems, by means of hierarchical task decompositions and state abstraction. This active area of research has

achieved mixed results, with algorithms and frameworks focusing on just one or two combinations of the different aspects of the problem. A single approach that can deal with structure discovery and its use, with both temporal and state abstraction, and that can provably learn and plan in polynomial time is still the main item in the research agenda of the field.

KEY TERMS

Factored-State Markov Decision Process: An extension to the MDP formalism used in Hierarchical RL where the transition probability is defined in terms of factors, allowing the representation to ignore certain state variables under certain contexts.

Hierarchical Reinforcement Learning: A subfield of reinforcement learning concerned with the discovery and use of task decomposition, hierarchical control, temporal and state abstraction (Barto & Mahadevan, 2003).

Hierarchical Task Decomposition: A decomposition of a task into a hierarchy of smaller subtasks.

Markov Decision Process: The most common formalism for environments used in reinforcement learning, where the problem is described in terms of a finite set of states, a finite set of actions, transition probabilities between states, a reward signal and a discount factor.

Reinforcement Learning: The problem faced by an agent that learns to a utility measure behavior from its interaction with the environment.

Semi-Markov Decision Process: An extension to the MDP formalism that deals with temporally extended actions and/or continuous time.

State-Space Generalization: The technique of grouping together states in the underlying MDP and treating them as equivalent for certain purposes.

High Level Design Approach for FPGA Implementation of ANNs

INTRODUCTION

Artificial neural networks (ANNs) are systems which are derived from the field of neuroscience and are characterized by intensive arithmetic operations. These networks display interesting features such as parallelism, classification, optimization, adaptation, generalization and associative memories. Since the McCulloch and Pitts pioneering work (McCulloch, W.S., & Pitts, W. (1943), there has been much discussion on the topic of ANNs implementation, and a huge diversity of ANNs has been designed (C. Lindsey & T. Lindblad, 1994). The benefits of using such implementations is well discussed in a paper by R. Lippmann (Richard P. Lippmann, 1984): "The great interest of building neural networks remains in the high speed processing that can be achieved through massively parallel implementation". In another paper Clark S. Lindsey (C.S Lindsey, Th. Lindblad, 1995) posed a real dilemma of hardware implementation: "Built a general, but probably expensive system that can be reprogrammed for several kinds of tasks like CNAPS for example? Or build a specialized chip to do one thing but very quickly, like the IBM ZISC Processor". To overcome this dilemma, most researchers agree that an ideal solution should relay the performances obtained using specific hardware implementation and the flexibility allowed by software tools and general purpose chips.

Since their commercial introduction in the mid-1980's, and due to the advances in the development

of both of the microelectronic technology and the specific CAD tools, FPGAs devices have progressed in an evolutionary and revolutionary way. The evolution process has allowed faster and bigger FPGAs, better CAD tools and better technical support. The revolution process concerns the introduction of high performances multipliers, Microprocessors and DSP functions. This has a direct incidence to FPGA implementation of ANNs and a lot of research has been carried to investigate the use of FPGAs in ANNs implementation (Amos R. Omandi & Jagath C. rajapakse, 2006).

Another attractive key feature of FPGAs is their flexibility, which can be obtained at different levels: exploitation of the programmability of FPGA, dynamic reconfiguration or run time reconfiguration (RTR), (Xilinx XAPP290, 2004) and the application of the **design for reuse** concept (Keating, Michael; Bricaud, Pierre, 2002).

However, a big disadvantage of FPGAs is the low level hardware oriented programming model needed to fully exploit the FPGA's potential performances.

High level based VHDL synthesis tools have been proposed to bridge the gap between the high level application requirements and the low level FPGA hardware but these tools are not algorithmic or application specific. Thus, special concepts need to be developed for automatic ANN implementation before using synthesis tools.

In this paper, we present a high level design methodology for ANN implementation that attempts to build a

bridge between the synthesis tool and the ANN design requirements. This method offers a high flexibility in the design while achieving speed/area performances constraints. The three implementation figures of the ANN based back propagation algorithm are considered. These are the off-type implementation, the on-chip global implementation and the dynamic reconfiguration choices of the ANN.

To achieve our goal, a design for reuse strategy has been applied. To validate our approach, three case studies are considered using the Virtex-II and Virtex-4 FPGA devices. A comparative study is done and new conclusions are given.

BACKGROUND

In this section, theoretical presentation of the **multilayer perceptron** (MLP) based back propagation algorithm is given. Then, discussion of the most related works to the topics of high level design methodology and ANNs frameworks are given.

Theoretical Background of the Back Propagation Algorithm

The back propagation is one of the well known algorithms that are used to train the MLP ANN network in a supervised mode. The MLP is executed in three phases: the *feed forward phase*, the *error calculation phase* and the *synaptic weight updating phase* (Freeman, J. A. and Skapura, D. M, 1991).

In the *feed forward phase*, a pattern x_i is applied to the input layer and the resulting signal is forward propagated through the network until the final outputs have been calculated; for each i (index of neuron) and j (index of layer)

$$\mu_j^l = \sum_{i=1}^{n_0} w_{ij}^l x_i \quad (1)$$

$$o_j^l = f(x_j) = \frac{1}{1 + \exp(-\mu_j)} \quad (2)$$

where, μ_j^l is the weighted sum of the synaptic weights and o_j^l is the output of the sigmoid activation function.

The *error calculation step*, computes the local error, δ for each layer starting from output back to input:

$$\delta_i^L = f'(u_i^L)(d_i - y_i) \quad (3)$$

$$\delta_j^{l-1} = f'(u_j^{l-1}) \sum_{i=1}^{N_l} w_{ij}^l \delta_i^l \quad 1 \leq i \leq N_l, \quad 1 \leq l \leq L \quad (4)$$

where, d_i is the desired output f' the derivative function of f

The *Weight update step* computes the weights updates according to:

$$w_{ij}^l(t+1) = w_{ij}^l(t) + \Delta w_{ij}^l(t) \quad (5)$$

$$\Delta w_{ij}^l(t) = \eta \delta_i^l y_j^{l-1} \quad (6)$$

where, η is the learning factor, Δw the variation of weights and l , the indices of the layers.

Background on ANN Frameworks

The most related works to ANNs frameworks are presented by (F. Schurmann & all, 2002), (M. Diepenhorst & all, 1999), and (J. Zhu & all, 1999).

In the other hand, and with the increasing complexity of FPGAs **circuits**, Core-based synthesis methodology is proposed as a new trend for efficient hardware implementation of FPGAs. In these tools a library of pre-designed IPs “Intellectual Property” cores are proposed. An example can be found in (Xilinx Core Generator reference) and (Opencores reference).

In the core based design methodology, efficient reuse is derived from the parameterized design with VHDL and its many flexible constructs and characteristics (i.e. abstraction, encapsulation, inheritance and reuse through attributes, package, procedures and functions). Beside this, the reuse concept is well suited for high regular and repetitive structures such as neural networks. However although all these advantages, seldom attention has been done to apply **design for reuse** for ANNs.

In this context our paper presents a new high level design methodology based upon the use of the **design for reuse** concept for ANNs.

In order to achieve this goal, the design must fulfill the following requirements (Keating, Michael; Bricaud, Pierre, 2002):

- The design must be block-based

- The design must be reconfigurable to meet the requirement of many different applications.
- The design must use standard interfaces.
- The code must be synthesizable at the RTL level.
- The design must be verified.
- The design must have robust scripts and must be well documented.

PRESENTATION OF THE PROPOSED DESIGN APPROACH

The proposed design approach is shown in Fig.1 as a process of flow. In this figure, the methodology used is based on a **top down design** approach in which the designer/user is guided step by step in the design process of the ANN.

First, the user is asked to select the dimension of the network. The next step involves selection of ANN implementation choices; these are the off chip

implementation, the global on chip implementation and implementation using run time reconfiguration (RTR). Thus a **Core** is generated for each type of implementation.

At this level, the user/designer can fix the parameters of the network, i.e. the number of neurons in each layer, synaptic values, multiplier type, data representation and precision. At the low level all the IP Cores that construct the neuron are generated automatically from the library of the synthesis tool which is in our case MENTOR GRAPHICS (Mentor Graphics user guide reference), and which also integrates the Xilinx IP Core Generator. In addition, for each IP Core, a graphical interface is generated to fix its parameters. Thus, the user/designer can change the network performances architecture by changing the IP cores that are stocked in the library. Then a VHDL code at the register transfer level (RTL) is generated for synthesis. Before, functional simulation is required. The result is a file netlist ready for place and rout followed by final FPGA prototyping on a board. Documentation is available at each level of the

Figure 1. The proposed design methodology

design process and the code is well commented. Thus, the **design for reuse** requirements is applied through the design process. In what follow, presentation of each implementation type is given.

The Feed Forward Off-Chip Implementation

Fig. 2 shows a top view of the feed forward core which is composed of a data path **module** and a control **module**. At the top level these two **modules** are represented by black boxes and only the neural network inputs and outputs signals are shown to the user/designer.

By clicking inside the boxes, we can get access to the network architecture which is composed of three layers represented by black boxes as shown in Fig. 3 (left side). By clicking inside each box, we can get access to the layer architecture which is composed of black boxes representing the neurons as shown in Fig. 3 (right side); and by clicking inside each neuron's box we can get access to the neuron hardware architecture as shown in Fig 4.

Each neuron implements the accumulated weight sum of equation (1) and the activation function of

equation (2). As shown in Fig. 4, the hardware model of the neuron is mainly based on a:

- Memory **circuit** where the final values of the synaptic weights are stocked,
- A multiply **circuit** (MULT) which computes the product of the stored synaptic weights with inputs data
- An accumulator circuit (ACUM) which computes the sum of the above products
- A **circuit** that approximates the activation function (example linear function or sigmoid function)
- A multiplexer **circuit** (MUX) in the case of serial transfer between inputs in the same neuron

The neural network architecture has the following properties:

- Computation between layers is done serially
- For the same layer, neurons are computed in parallel
- For the same neuron, only one multiplier and one accumulator (MULT + ACUM=MAC) are used to compute the product sum.

Figure 2. The feed forward core module using the mentor graphics design tool

Figure 3. The ANN architecture

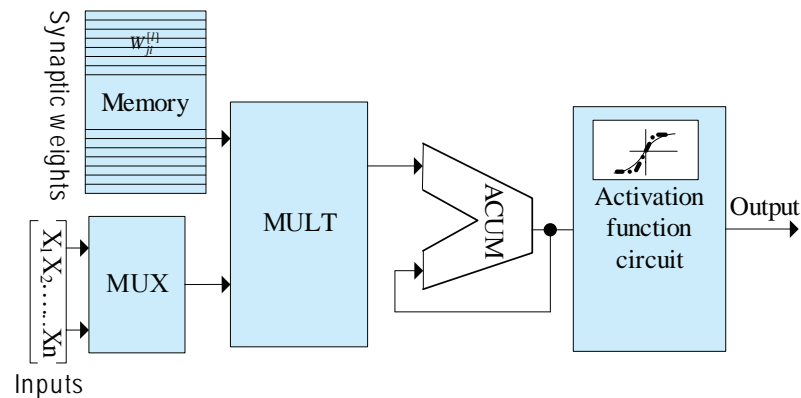

Figure 4. Equivalent hardware architecture of the neuron

- Each multiplier is connected to a memory. The depth of each memory is equal to the number of neurons constituting the layer
- The whole network is controlled by a control unit module.

Each **circuit** that constructs the neuron is an IP **core** “Intellectual Property” that can be generated from the Xilinx Core Generator.

The feed forward control **module** is composed of three phases: control of the neuron, control of the

layer and control of the network. Considering the fact that neurons work in parallel, so control of the layer is similar to the control of the neuron plus the multiplexer's control. Control of the neuron is divided into four phases: start, initialization, synaptic multiplication/accumulation and storage of the weighted sum. The first state diagram of the feed forward control module which was designed, was based on the Moore machine in which the system vary only when its state change. The drawback of this machine is that it is not generic. For example, (load=0, reset=0) allows the accumulator to add a value present at the input register. This accumulated value must be done as many times as the number of neurons in the previous layer. Thus, if we change the number of neurons from one layer to another one, we have to change all the flow state of the control module. To overcome this problem, the Moor machine is replaced by the Mealy machine in which we add a counter program with a generic value M and a transition variable Max such that:

$$\begin{cases} \text{if output_counter} = M \rightarrow Max = 1 \\ \text{else} \rightarrow Max = 0 \end{cases}$$

where the value of M is done equal to the number of neuron.

By using this strategy, we obtain an architecture that has two important key features: genericity and flexibility. Genericity is related to the data word size, precision, and memory depth which are kept as generic parameters at the top level of the VHDL description. The flexibility feature is related to the size of the network (the number of neurons in each layer), thus it is possible to add neurons by simple copy/past of the neurons boxes or cores and it is also possible to remove them by simple cut operation of the boxes. It is also possible to use other IP **cores** from the library (example replace parallel MULT with pipeline MULT) to change the performances of the network without changing the VHDL code. Thus, the **design for reuse** concept is applied.

The Direct On-Chip Implementation Strategy

In this section, we propose the equivalent architecture for implementation of the three successive phases of the back propagation algorithm. Fig.5 depicts the pro-

posed architecture which is composed of a feed forward module, an Error-calculation module and an Update module. The set of the three modules is controlled by a global control unit. The feed forward **module** computes equations (1) and (2). The Error module computes equations (3) and (4) and the Update module computes equations (5) and (6). Each **module** exhibits a high degree of regularity of the structure, modularity and repeatability which make the whole ANN a good candidate for the application of the design for reuse concept. As in the off-chip implementation case, first the unit control unit has been done using a Moore machine that integrates control of the three **modules**: feed forward, error and update modules. In order to achieve reuse, we have replaced the Moore machine by a Mealy machine. Thus, the size of the network can be modified by simple copy/past or remove operations of the boxes.

The Run Time Reconfiguration Strategy

Our strategy for run time reconfiguration follows the following steps: first the feed forward and the global control modules are configured. The results are stored in the Bus macro module of the Virtex FPGA device. In the next step, the feed forward module is reset from the FPGA and the Update and Error modules are configured. The generated results are stored in the Bus macro modules and the same procedure is applied to the next training example of the ANN. A more detailed description is given in (N. Izeboudjen and all, 2007).

Performance Evaluation

In this section, we discuss the performance of the three implementation figures of the back propagation algorithm. The parameters to be considered are the number of configurable logic blocs (CLB), the time response (TR) and the number of Million connexions per second (MCPS). A comparison of these parameters is done between the Virtex-II and Virtex-4 families. Functional simulation is achieved using ModelSim simulator (ModelSim user guide reference). The RTL synthesis is achieved using the Mentor graphics synthesis tool (Mentor Graphics synthesis tool user guide reference) and for final implementation, the ISE foundation place and rout (8.2) tool is used (ISE foundation user guide reference).

Figure 5. Architecture of the BP algorithm

Our first application is an ANN classifier that is used to classify heart coronary diseases. The network has been trained off chip using the MATLAB 6.5 tool. After training the dimension of the network as well as the synaptic weight were fixed. The network has a dimension of (1, 8, 1) and the synaptic weights have a data width of 24 bits. For this application we selected the circuits XC2V1000 and XC4VLX15 devices, of Virtex-II and Virtex-4 respectively. Synthesis results show that the XC2V1000 circuit consume 99% in terms of (CLB), the time response TR = 44.46 (ns) while the MCPS=360. Concerning the XC4VLX15, it consumes 82% in term of CLB, TR= 26.76 (ns) and MCPS= 597. Thus, the XC4VLX15 achieves better performances in term of area (gain 19% of CLB in term of area), the speed rate is 1.6 and MCPS rate is 1.6.

Our second application is the classical (2, 2, 1) "XOR" ANN which is used as a benchmark for non-linearly separable problems. The general on chip learning implementation has been applied to the network. It is to be mentioned that area constraints could not be met for

the first family XC2V1000 as well as the XC4VLX15, and we have tried several families until we fixed the XC4VLX80 for Virtex-4 and the XC2V8000 for Virtex-II. Synthesis results show that the XC2V8000 circuit consume 22% in terms of (CLB), the time response TR= 59.5 (ns) while the MCPS=202. Concerning the XC4VLX80, it consumes 30% in term of (CLB), TR = 47.93 (ns) and MCPS= 250. From these results we can conclude that with the Virtex-II family we can gain 8% of (CLB) in term of area ; this is due to the fact that the Virtex-II integrates more multipliers than the Virtex-4 and in which the MAC component is integrated into the DSP48 (XC4VLX80 has 80 MAC DSP and XC2V8000 has 168 bloc multipliers). But the Virtex-4 circuit is faster than the Virtex-II and can achieve more MCPS (rate of ~1.24). The on chip implementation requires a lot of multipliers and this is why, we recommend using it if the timing constraints are not critical.

In the third application, three arbitrary networks are used to show the performance of the (RTR) over the global implementation. These are a (3,3,3) network,

a (16,16,16) network and a (16,64,8) network. The results show that when the size of the network is big it is difficult to implement the whole RPG into one FPGA. With the RTR we can achieve more than 30% reduction in the area and more than 40% increase in speed and MCPS.

FUTURE TRENDS

The proposed ANN environment is still under construction. The design approach is based on the use of pre-designed IP **cores** which are generated from the Xilinx **Core** generator tool. Our next objective is to enrich and enhance the library of the IP cores, especially in the case of implementation of the activation function (sigmoid, linear transfer circuits), and to evaluate and compare the performances of the ANN regarding others pre-designed IP **cores**.

Also, we plan to extend the reuse concept of the ANN to other ANNs algorithms (Kohonen, Hopfield networks)

Concerning the run-time reconfiguration (RTR), the next step is to integrate the RTR design approach with the planeAhead design tool (PlanAhead user guide reference).

As future work, we plan to evaluate and analysis the cost of the design for reuse concept applied to ANNs

CONCLUSION

Through this paper, we have presented a successful design approach for FPGA implementation of ANNs. We have applied a **design for reuse** strategy and parametric design to achieve our goal. The proposed methodology offers high flexibility because the size of the ANN can be changed by simple copy/remove of the neurons **cores**. In addition the format, data widths and precision are considered as generic parameters. Thus, different applications can be targeted in a reduced design time. As for the three applications, the first conclusion is that the new Virtex-4 FPGA devices achieve faster networks comparing to Virtex-II; but regarding to the area; i.e. number of CLBs, the Virtex-II is better. Thus in our opinion, the Virtex-II is well suited as a platform to experiment ANN implementations. This can help to give new directions for future work.

INTRODUCTION

Biological vision processes are usually characterized by the following different phases:

- Awareness: natural or artificial agents operating in dynamic environments can benefit from a, possibly rough, global description of the surroundings. In human this is referred to as peripheral vision, since it derives from stimuli coming from the edge of the retina.
- Attention: once an interesting object/event has been detected, higher resolution is required to set focus on it and plan an appropriate reaction. In human this corresponds to the so-called foveal vision, since it originates from the center of the retina (fovea).
- Analysis: extraction of detailed information about objects of interest, their three-dimensional structure and their spatial relationships completes the vision process. Achievement of these goals requires at least two views of the surrounding scene with known geometrical relations. In humans, this function is performed exploiting binocular (stereo) vision.

Computer Vision has often tried to emulate natural systems or, at least, to take inspiration from them. In fact, different levels of resolution are useful also in machine vision. In the last decade a number of studies dealing with multiple cameras at different resolutions have appeared in literature. Furthermore, the ever-growing computer performances and the ever-decreasing cost of video equipment make it possible to develop systems

which rely mostly, or even exclusively, on vision for navigating and reacting to environmental changes in real time. Moreover, using vision as the unique sensory input makes artificial perception closer to human perception, unlike systems relying on other kinds of sensors and allows for the development of more direct biologically-inspired approaches to interaction with the external environment (Trullier 1997).

This article presents HOPS (Hybrid Omnidirectional Pin-hole Sensor), a class of dual camera vision sensors that try to exalt the connection between machine vision and biological vision.

BACKGROUND

In the last decade some investigations on hybrid dual camera systems have been performed (Nayar 1997; Cui 1998; Adorni 2001; Adorni 2002; Adorni 2003; Scotti 2005; Yao 2006). The joint use of a moving standard camera and of a catadioptric sensor provides these sensors with their different and complementary features: while the traditional camera can be used to acquire detailed information about a limited region of interest ("foveal vision"), the omnidirectional sensor provides wide-range, but less detailed, information about the surroundings ("peripheral vision"). Possible employments for this class of vision systems are video surveillance applications as well as mobile robot navigation tasks. Moreover, their particular configuration makes it possible to realize different strategies to control the orientation of the standard camera; for example, scattered focus on different objects permits to perform recognition/classification tasks while continu-

ous movements allow to track any interesting moving object. Three-dimensional reconstruction based on stereo vision is also possible.

HOPS: HYBRID OMNIDIRECTIONAL PIN-HOLE SENSOR

This article is focused on the latest prototype of the HOPS (Hybrid Omnidirectional-Pinhole Sensor) sensor (Adorni 2001; Adorni 2002; Adorni 2003, Cagnoni 2007). HOPS is a dual camera vision system that achieves a high-resolution 360-degrees field of view as well as 3D reconstruction capabilities. The effectiveness of this hybrid sensor derives from the joint use of a traditional camera and a central catadioptric camera which both satisfy the single-viewpoint constraint. Having two different viewpoints from which the world is observed, the sensor can therefore act as a stereo pair finding effective applications in surveillance and robot navigation.

To create a handy versatile system that could meet the requirements of the whole vision process in a wide variety of applications, HOPS has been designed to be considered as a single integrated object: one of the most direct advantages offered by this is that, once it is

assembled and calibrated, it can be placed and moved anywhere (for example in the middle of a room ceiling or on a mobile robot) without any need for further calibrations.

Figure 1 shows the latest two HOPS prototypes. In the one that has been used for the experiments reported here, the traditional camera which, in this version, cannot rotate, has been placed on top and can be pointed downwards with an appropriate fixed tilt angle to obtain a high-resolution view of a restricted region close to the sensor. In the middle, one can see the catadioptric camera consisting of a traditional camera pointing upwards to a hyperbolic mirror hanging over it and held by a plexiglas cylinder. As can be observed, the mirror can be moved up and down to permit optimal positioning (Swaminathan 2001; Strelow 2001) during calibration.

Moreover, to avoid undesired light reflections on the internal surface of the Plexiglas cylinder, a black needle has been placed on the mirror apex as suggested in (Ishiguro 2001). Finally, in the lower part, some circuits generate video synchronization signals and allow for external connections.

The newer version of HOPS (see Figure 1, right) overcomes some limitations of the present one. It uses two digital high-resolution Firewire cameras,

Figure 1. The two latest versions of the HOPS sensor: the one used for experiments (left) and the newest version (right) which is currently being assembled and tested.

in conjunction with mega-pixel lenses characterized by a very low TV-distortion, to achieve better image quality. Furthermore, in this new version the traditional camera is hung to a stepper motor, controlled via a USB interface, and therefore is able to rotate. This time the traditional camera has been placed below the catadioptric part: this makes it possible to have no wires within the field of view of the omnidirectional image besides allowing, in surveillance applications, to see also the blind area of the omnidirectional view due to the reflection of the camera on the mirror.

Sensor Calibration

In order to extract metric information from two-dimensional images, one must perform a calibration of the camera and estimate the geometric parameters needed to describe image formation. Therefore, after calibration, relationships between points on images and their real position in the 3D space can be expressed by mathematical equations which can solve metric problems.

Sensor calibration can be based on a standard Photogrammetric Calibration (Kraus 1993; Zhang 2000) using a heavily structured environment with grids of points of known coordinates. First, the two cameras are calibrated independently, before assembling them on the sensor, to estimate their intrinsics as well as the radial distortion introduced by the optics. Then, the mirror is accurately positioned with respect to the camera in order to achieve single-viewpoint vision for the catadioptric

part of the sensor as described by (Benosman 2001). The last, but probably most important, phase of the calibration is aimed at detecting geometric relationships between the traditional image and the omnidirectional one: once again, a set of known points was used to estimate the parameters of the mapping.

Notice that the relationships that were computed between the two views are constant in time because of the sensor structure. In this way, once the calibration procedure is over, no external fixed references are needed any longer, and one can place the sensor anywhere and perform stereo vision tasks without needing any further calibration.

Mirror to Camera Positioning

To position the hyperbolic mirror with respect to the standard camera and achieve the single-viewpoint characteristic for the catadioptric part of the sensor, one can operate as follows.

Supposing that the single view-point constraint is satisfied, and since the mirror profile is known, the camera calibration data and some simple equations can be used to calculate the expected projections of any known 3D point set onto the omnidirectional image. To verify the correctness of the relative mirror-to-camera positioning, a calibration box has been built with grids of known coordinates painted on its inner walls. Hence, after placing the sensor into it, the mirror can be manually moved until the grids appearing on the image taken in real time match the theoretical

Figure 2. Mirror position calibration: the sensor inside the calibration box (left) and the acquired omnidirectional image (right) with the correct grid positions superimposed in white.

ones super-imposed over it as they should appear if the mirror had been correctly placed (see Figure 2). This is a very cheap method which, however, yields very good results.

Joint Camera Calibration

To obtain a fully effective stereo system it is essential to make a joint camera calibration to extract information about the relative positioning of the camera pair. Usually, the internal reference frame of one of the two cameras is chosen as the global reference for the pair: since two different kinds of cameras are available, the simplest choice is to set the omnidirectional camera's frame as the global reference for the whole sensor. Using once again the above-mentioned grids of points, images pair (omnidirectional and traditional) of grids lying on different (parallel) planes with known relative positions are acquired. Once 3D coordinates of points positions, referred to the sensor reference frame, have been estimated through the omnidirectional image, solving for geometric constraints between points projections in the traditional image permits to estimate the relative position of the traditional camera.

To take the standard camera rotation into consideration, its position has to be described by a more complex transformation than a simply fixed rototranslation: the geometric and kinematic coupling between the two cameras has to be understood and modeled with more parameters. Obviously, this requires that images be taken with the traditional camera in many different positions.

After this joint camera calibration, HOPS can be used to perform metric measurements on the images, obtaining three-dimensional data referred to its own global reference frame: this means that no further calibrations are needed to take sensor displacements into account.

Perspective Reprojections & Inverse Perspective Mapping

One of the opportunities offered by a perspective image is the possibility to apply an Inverse Perspective Mapping (IPM) transformation (Little 1991) to obtain a different image in which the information content is homogeneously distributed among all pixels. Since central catadioptric cameras are characterized by a single viewpoint, the images acquired by them are perspective

images suitable to be used for IPM. Choosing a virtual image plane as the new domain for the IPM, a perspective reprojection similar to traditional images can be obtained from part of those omnidirectional images.

Figure 3 shows a pair of images acquired by HOPS and a perspective reconstruction of the omnidirectional view obtained applying an IPM on the corresponding area seen by the traditional camera. As can be noticed, the difference in resolution between the two perspective views is considerable. Choosing a horizontal plane as reference for the IPM, it is possible to obtain something very similar to an orthographic view of that area, usually referred to as "bird's eye view". If the floor is used as reference to perform IPM on both images, it is possible to extract useful information about objects/obstacles surrounding the system (Bertozzi 1998).

3D Reconstruction Tests

To verify the correctness of the calibration process, an estimation of the positions of points in a three-dimensional space can be performed along with other tests. After capturing one image from each of the two views, the points in the test pattern are automatically detected and for each one the light rays from which it was generated are computed based on the projection model obtained during calibration. Since the estimated homologous rays are usually skew lines, the shortest segment joining the two rays can be found and its middle point used as an estimate of the point's 3D position.

In Table 1, results obtained using a 4x3 point test-pattern with 60 mm between point centers are reported. Even if the origin of the sensor reference system is physically inaccessible and no high-precision instruments were available, this pattern was placed as accurately as possible 390 mm perpendicularly ahead of the sensor itself (along the y direction in the chosen reference frame) and centered along the x direction: the z coordinates of the points in the top row were measured to be equal to 55 mm. This set-up is reflected by the estimated values for the first experiment reported in Table 1. More relevantly, the mean distance between points was estimated to be 59.45 mm with a standard deviation $\sigma = 1.14$: those values are fully compatible with the resolution available for measuring distances on the test pattern and with the mirror resolution (also limited by image resolution).

In a second experiment, a test-pattern with six points spaced by 110 mm, located about 1 m ahead, 0.25 m

Figure 3. Omnidirectional image (above, left) and traditional image (above, right) acquired by HOPS. Below a perspective reconstruction of part of the omnidirectional one is shown.

to the right and a bit below the sensor, has been used. In the lower part of Table 1 the estimated positions are shown: the estimated mean distance was 109.09 mm with a standard deviation $\sigma = 8.89$. In another test with the same pattern located 1.3 m ahead, 0.6 m to the left and 0.5 m below the sensor (see Figure 4) the estimated mean distance was of about 102 mm with a standard deviation $\sigma = 9.98$.

It should be noticed that, at those distances, taking into account image resolution as well as the mirror profile, the sensor resolution is of the same order of magnitude as the errors obtained. Furthermore, the method used to find the center of circles suffers from luminance and contrast variations: substituting circles with adjacent alternate black and white squares and

using a corner detector capable of sub-pixel accuracy would probably yield better results.

FUTURE TRENDS

A field which nowadays draws great interest is autonomous vehicle navigation. Even if at the moment there are still many problems to be solved before seeing autonomous public vehicles, industrial applications are already possible. Since results in omnidirectional visual servoing and ego-motion estimation are also applicable to hybrid dual camera systems, and many more opportunities are offered by the presence of a second high-resolution view, the use of such devices in this field

Table 1. 3D estimation results: the tables show the estimated positions obtained. The diagrams below them show the estimated distances between points on the test-pattern. All values are in mm.

Figure 4. Omnidirectional image (left) and traditional image (right) acquired for a 3D stereo estimation test

is desirable. Even if most applications of these systems are related with surveillance, they could be applied even more directly to robot-aided human activities, since robots/vehicles involved in these situations are less critical and their controllability is easier.

CONCLUSIONS

The Hybrid Omnidirectional Pin-hole Sensor (HOPS) dual camera system has been described. Since its joint camera calibration leads to a fully calibrated hybrid stereo pair from which 3D information can be extracted, HOPS suits several kinds of applications. For example, it can be used for surveillance and robot self-localization or obstacle detection, offering the possibility to integrate stereo sensing with peripheral/foveal active vision strategies: once objects or regions of interest are localized on the wide-range sensor, the traditional camera can be used to enhance the resolution with which these areas can be analyzed.

Tracking of multiple objects/people relying on high-resolution images for recognition and access control or estimating velocity, dimensions and trajectories are some examples of surveillance tasks for which HOPS is suitable. Accurate obstacle detection, landmark localization, robust ego-motion estimation or three-dimensional environment reconstruction are other examples of possible applications related to (autonomous/holonomous) robot navigation in semi-structured or completely unstructured environments. Some preliminary experiments have been performed to solve both surveillance and robot navigation with encouraging results.

KEY TERMS

Camera Calibration: A procedure used to obtain geometrical information about image formation in a specific camera essential to relate metric distances on the image to distances in the real world. Anyway, some a priori information is needed to reconstruct the third dimension from only one image.

Holonomous Robot: A robot with an unconstrained freedom of movement with no preferential direction.

This means that, from a standing position, it can move as easily in any direction.

Inverse Perspective Mapping (IPM): A procedure which allows for perspective effect to be removed from an image by homogeneously redistributing the information content of the image plane into a new two-dimensional domain.

Lens Distortion: Optical errors in camera lenses, usually due to mechanical misalignment of its parts, can cause straight lines in the observed scene to appear curved in the captured image. The deviation between the theoretical image and the actual one is mostly to be attributed to lens distortion.

Pin-Hole Camera: A camera that uses a tiny hole (the pin-hole) to convey all rays from the observed scene to the image plane. The smaller the pin-hole, the sharper the picture. Pin-hole cameras achieve a potentially infinite depth of field. Because of its geometric simplicity, the “pin-hole model” is used to describe most traditional cameras.

Single Viewpoint Constraint: When all incoming principal light rays of a lens intersect at a single point, an image with a non-distorted metric content is obtained. In this case all information contained in this image is seen from this view-point.

Visual Servoing: An approach to robot control based on visual perception: a vision system extracts information from the surrounding environment to localize the robot and consequently servoing its position.

Hybrid Dual Camera Vision Systems

INTRODUCTION

Many of the known visual systems in nature are characterized by a wide field of view allowing animals to keep the whole surrounding environment under control. In this sense, dragonflies are one of the best examples: their compound eyes are made up of thousands of separate light-sensing organs arranged to give nearly a 360° field of vision. However, animals with eyes on the sides of their head have high periscopy but low binocularity, that is their views overlap very little. Differently, raptors' eyes have a central part that permits them to see far away details with an impressive resolution and their views overlap by about ninety degrees. Those characteristics allow for a globally wide field of view and for accurate stereoscopic vision at the same time, which in turn allows for determination of distance, leading to the ability to develop a sharp, three-dimensional image of a large portion of their view.

In mobile robotics applications, autonomous robots are required to react to visual stimuli that may come from any direction at any moment of their activity. In surveillance applications, the opportunity to obtain a field of view as wide as possible is also a critical requirement. For these reasons, a growing interest in omnidirectional vision systems (Benosman 2001), which is still a particularly intriguing research field, has emerged. On the other hand, requirements to be able to carry out object/pattern recognition and classification tasks are opposite, high resolution and accuracy and low distortion being possibly the most important ones. Finally, three-dimensional information extraction can be usually achieved by vision systems that combine the use of at least two sensors at the same time.

This article presents the class of hybrid dual camera vision systems. This kind of sensors, inspired by existing visual systems in nature, combines an omnidirectional sensor with a perspective moving camera. In this way it is possible to observe the whole surrounding scene at low resolution, while, at the same time, the perspective camera can be directed to focus on objects of interest with higher resolution.

BACKGROUND

There are essentially two ways to observe a very wide area. It is possible to use many cameras pointed on non-overlapping areas or, conversely, a single camera with a wide field of view. In the former case, the amount of data to be analyzed is much bigger than in the latter one. In addition, calibration and synchronization problems for the camera network have to be faced. On the other hand, in the second approach the system is cheaper, easy to calibrate, while the analysis of a single image is straightforward. In this case, however, the disadvantage is a loss of resolution at which objects details are seen, since a wider field of view is projected onto the same area of the video sensor and thus described with the same amount of pixel as for a normal one. This was clear since the mid 1990s with the earlier experiments with omnidirectional vision systems. Consequently a number of studies on omnidirectional sensors "enriched" with at least one second source of environmental data arose to achieve wide fields of view without loss of resolution. For example some work, oriented to robotics applications, has dealt with a catadioptric camera working in conjunction with a laser scanner as, to cite

only few recent, in (Kobilarov 2006; Mei 2006). More surveillance application-oriented work has involved multi-camera systems, joining omnidirectional and traditional cameras, while other work dealt with geometric aspects of hybrid stereo/multi-view relations, as in (Sturm 2002; Chen 2003).

The natural choice to develop a cheap vision system with both omni-sight and high-detail resolution is to couple an omnidirectional camera with a moving traditional camera. In the sequel, we will focus on this kind of systems that are usually called “hybrid dual camera systems”.

Omnidirectional Vision

There are two ways to obtain omnidirectional images. With a special kind of lenses mounted on a standard camera, called “fisheye lenses”, it is possible to obtain a field of view up to about 180-degrees in both directions. The widest fisheye lens ever produced featured a 220-degrees field of view. Unfortunately, it is very difficult to design a fisheye lens that satisfies the single viewpoint constraint. Although images acquired by fisheye lenses may prove to be good enough for some visualization applications, the distortion compensation issue has not been solved yet, and the high unit-cost is a major drawback for its wide-spread applications.

Combining a rectilinear lens with a mirror is the other way to obtain omnidirectional views. In the so called “catadioptric lenses” a convex mirror is placed in front of a rectilinear lens achieving a field of view possibly even larger than with a fisheye lens. Using particularly shaped mirrors precisely placed with

respect to the camera is also possible to satisfy the single viewpoint constraint and thus to obtain an image which is perspectively correct. Moreover, catadioptric lenses are usually cheaper than fisheye ones. In Figure 1 a comparison between these two kinds of lenses can be seen.

OVERVIEW OF HYBRID DUAL CAMERA SYSTEMS

The first work concerning hybrid vision sensors is probably the one mentioned in (Nayar 1997) referred to as “Omnidirectional Pan/Tilt/Zoom System” where the PTZ unit was guided by inputs obtained from the omnidirectional view. The next year (Cui 1998) presented a distributed system for indoor monitoring: a peripheral camera was calibrated to estimate the distance between a target and the projection of the camera on the floor. In this way, they were able to precisely direct the foveal sensor, of known position, to the target and track it. A hybrid system for obstacle detection in robot navigation was described in (Adorni 2001) few years later. In this work, a catadioptric camera was calibrated along with a perspective one as a single sensor: its calibration procedure permitted to compute an Inverse Perspective Mapping (IPM) (Little 1991) based on a reference plane, the floor, for both images and hence, thanks to the cameras’ disparity, to detect obstacles by computing the difference between the two images. While this was possible only within the common field of view of the two cameras, awareness or even tasks such as ego-motion estimation were potentially pos-

Figure 1. Comparison between image formation in fisheye lenses (left) and catadioptric lenses (right)

Figure 2. A pair of images acquired with the hybrid system described in (Cagnoni 2007). The omnidirectional image (left) and the perspective image (right). The different resolution of the two images is clearly visible.

sible thanks to the omni-view. This system was further improved and mainly tested in RoboCup¹ applications, (Adorni 2002; Adorni 2003; Cagnoni 2007). In Figure 2 it is possible to see a pair of images acquired with such a system.

Some recent work has concentrated on using dual camera systems for surveillance applications. In (Scotti 2005), when some alarm is detected on the omnidirectional sensor, the PTZ camera is triggered and the two views start to track the target autonomously. Acquired video sequences and other metadata, like object classification information, are then used to update a distributed database to be queried later by users. Similarly in (Yao 2006), after the PTZ camera is triggered by the omnidirectional one, the target is tracked independently on the two views, but then a modified Kalman filter is used to perform data fusion: this approach achieves an improved tracking accuracy and permits to resolve occasional occlusions leading to a robust surveillance system.

FUTURE TRENDS

Nowadays public order keeping, private property access control and security video surveillance are reasons for which we need to surveil wide areas of our environment. Surveillance is an ever growing market and automatic surveillance is an interesting challenge: many projects are oriented in this direction and in some of them an

important role is already played by hybrid dual camera systems. The monitoring system installed between Eagle Pass, Texas, and Piedras Negras, Mexico, by engineers of the Computer Vision and Robotics Laboratory at the University of California, San Diego, affiliated with the California Institute for Telecommunications and Information Technology, is an example of a very complex surveillance system in which hybrid dual camera systems are involved (Hagen 2006). Because of the competitive cost, the compactness and the opportunities offered by these systems, they are likely to be used more and more in the future in intelligent surveillance systems.

Another field subjected to great interest is autonomous vehicle navigation. Even if at the moment there are still many problems to be solved before seeing autonomous public vehicles, industrial applications are already possible. Since omnidirectional visual servoing and ego-motion estimation can actually be implemented also using hybrid dual camera systems, and many more opportunities are offered by the presence of a second high-resolution view, their future involvement in this field is desirable.

CONCLUSIONS

The class of hybrid dual camera systems has been described and briefly overviewed. The joint use of a standard camera and of a catadioptric sensor provides

this kind of sensors with their different and complementary features: while the traditional camera can be used to acquire detailed information about a limited region of interest (“foveal vision”), the omnidirectional sensor provides wide-range, but less detailed information about the surroundings (“peripheral vision”).

Tracking of multiple objects/people relying on high-resolution images for recognition and access control or estimating object/people velocity, dimensions and trajectory are some examples of possible automatic surveillance tasks for which hybrid dual camera systems are suitable. Furthermore, their use in (autonomous) robot navigation, allows for accurate obstacle detection, egomotion estimation and three-dimensional environment reconstruction. With one of these sensors on board, a mobile robot can be provided with all the necessary information needed to navigate safely in a dynamic environment.

KEY TERMS

Camera Calibration: A procedure used to obtain geometrical information about image formation in a specific camera. After calibration, it is possible to relate metric distances on the image to distances in the real world. In any case only one image is not enough to reconstruct the third dimension and some a priori information is needed to accomplish this capability.

Catadioptric Camera: A camera that uses in conjunction catoptric, reflective, lenses (mirrors) and dioptric, refractive, lenses. Usually the purpose of these cameras is to achieve a wider field of view than the one obtained by classical lenses. Even if the field of view of a lens could be improved with any convex surface mirror, those of greater interest are conic, spherical, parabolic and hyperbolic-shaped ones.

Central Catadioptric Camera: A camera that combines lenses and mirrors to capture a wide field of view through a central projection (i.e. a single viewpoint). Most common examples use paraboloidal or hyperboloidal mirrors. In the former case a telecentric lens is needed to focalize parallel rays reflected by the mirror and there are no constraints for mirror to camera relative positioning: the internal focus of the parabola acts as the unique viewpoint; in the latter case it is possible to use a normal lens, but mirror to camera positioning is critical for achieving a single viewpoint: it is essential

that the principal point of the lens coincides with the external focus of the hyperboloid to let the internal one be the unique viewpoint for the observed scene.

Omnidirectional Camera: A camera able to see in all directions. There are essentially two different methods to obtain a very wide field of view: the older one involves the use of a special type of lens, usually referred to as fisheye lens, while the other one uses in conjunction rectilinear lenses and mirrors. Lenses obtained in the latter case are usually called catadioptric lenses and the camera-lens ensemble is referred to as catadioptric camera.

PTZ Camera: A camera able to pan left and right, tilt up and down, and zoom. It is usually possible to freely control its orientation and zooming status at a distance through a computer or a dedicated control system.

Stereo Vision: A visual perception process that exploits two different views to achieve depth perception. The difference between the two images, usually referred to as binocular disparity, is interpreted by the brain (or by an artificial intelligent system) as depth.

Single Viewpoint Constraint: To obtain an image with a non-distorted metric content, it is essential that all incoming principal light rays of a lens intersect at a single point. In this case a fixed viewpoint is obtained and all the information contained in an image is seen from this point.

Hybrid Meta-Heuristics Based System for Dynamic Scheduling

Ana Maria Madureira

Polytechnic Institute of Porto, Portugal

INTRODUCTION

The complexity of current computer systems has led the software engineering, distributed systems and management communities to look for inspiration in diverse fields, e.g. robotics, artificial intelligence or biology, to find new ways of designing and managing systems. Hybridization and combination of different approaches seems to be a promising research field of computational intelligence focusing on the development of the next generation of intelligent systems.

A manufacturing system has a natural dynamic nature observed through several kinds of random occurrences and perturbations on working conditions and requirements over time. For this kind of environment it is important the ability to efficient and effectively adapt, on a continuous basis, existing schedules according to the referred disturbances, keeping performance levels. The application of Meta-Heuristics to the resolution of this class of **dynamic scheduling** problems seems really promising.

In this article, we propose a hybrid Meta-Heuristic based approach for complex scheduling with several manufacturing and assembly operations, in dynamic Extended Job-Shop environments. Some self-adaptation mechanisms are proposed.

BACKGROUND

Scheduling Problem

The planning of **Manufacturing Systems** involves frequently the resolution of a huge amount and variety of combinatorial optimisation problems with an important impact on the performance of manufacturing organisations. Examples of those problems are the sequencing and scheduling problems in manufacturing management, routing and transportation, layout design and timetabling problems.

Scheduling can be defined as the assignment of time-constrained jobs to time-constrained resources within a pre-defined time framework, which represents the complete time horizon of the schedule. An admissible schedule will have to satisfy a set of constraints imposed on jobs and resources. So, a scheduling problem can be seen as a decision making process for operations starting and resources to be used. A variety of characteristics and constraints related with jobs and production system, such as operation processing time, release and due dates, precedence constraints and resource availability, can affect scheduling decisions (Leung, 2004) (Brucker, 2004) (Blazewicz, Ecker & Trystrams, 2005) (Pinedo, 2005).

Real world scheduling requirements are related with complex systems operated in dynamic environments. This means that they are frequently subject to several kinds of random occurrences and perturbations, such as new job arrivals, machine breakdowns, employees sickness, jobs cancellation and due date and time processing changes, causing prepared schedules becoming easily outdated and unsuitable. Scheduling under this environment is known as dynamic.

Dynamic scheduling problems may be classified under deterministic, when release times and all other parameters are known and fixed, and under **non-deterministic** when some or all system and job parameters are uncertain, such as when jobs arrive randomly to the system, over time.

Traditional **heuristic** scheduling methods, encounter great difficulties when they are applied to some real-world situations. This is for three main reasons. Firstly, traditional scheduling methods use simplified and deterministic theoretical models, where all problem data are known before scheduling starts. However, many real world optimization problems are dynamic and non-deterministic and, in which changes may occur continually. In practice, static scheduling is not able to react dynamically and rapidly in the presence of dynamic information not previously foreseen in the current schedule.

Secondly, most of the approximation methods proposed for the Job-Shop Scheduling Problems (JSSP) are oriented methods, i.e. developed specifically for the problem in consideration. Some examples of this class of methods are the priority rules and the Shifting Bottleneck (Pinedo, 2005).

Finally, traditional scheduling methods are essentially centralized in the sense that all the computations are carried out in a central computing and logic unit. All the information concerning every job and every resource has to go through this unit. This centralized approach is especially susceptible to problems of tractability, because the number of interacting entities that must be managed together is large and leads to a combinatorial explosion. Particularly since, a detailed schedule is generated over a long time horizon, and planning and execution are carried out in discrete buckets of time. Centralized scheduling is therefore large, complex, and difficult to maintain and reconfigure. On the other hand, the inherent nature of much industrial and service process is distributed. Consequently, traditional methods are often too inflexible, costly, and slow to satisfy the needs of real-world scheduling systems.

By exploiting problem-specific characteristics, classical optimisation methods are not enough for the efficient resolution of those problems or are developed for specific situations (Leung, 2004) (Brucker, 2004) (Logie, Sabaz & Gruver, 2004) (Blazewicz, Ecker & Trystrams, 2005) (Pinedo, 2005).

Meta-Heuristics

As a major departure from classical techniques, a **Meta-heuristic** (MH) method implies higher-level strategy controlling lower-level **heuristic** methods. Meta-heuristics exploit not only the problem characteristics but also ideas based on **artificial intelligence** rationale, such as different types of memory structures and learning mechanisms, as well as the analogy with other optimization methods found in nature.

The interest of the Meta-Heuristic approaches is that they converge, in general, to satisfactory solutions in an effective and efficient way (computing time and implementation effort). The family of MH includes, but it is not limited to Tabu Search, Simulated Annealing, Soft Computing, Evolutionary Algorithms, Adaptive Memory procedures, Scatter Search, Ant Colony Optimization, Swarm Intelligence, and their hybrids.

For literature on this subject, see for example (Glover & Gary, 2003) and (Gonzalez, 2007).

In last decades, there has been a significant level of research interest in **Meta-Heuristic** approaches for solving large real world scheduling problems, which are often complex, constrained and dynamic. Scheduling algorithms that achieve good or near optimal solutions and can efficiently adapt them to perturbations are, in most cases, preferable to those that achieve optimal ones but that cannot implement such an adaptation. This is the case with most algorithms for solving the so-called static scheduling problem for different setting of both single and multi-machine systems arrangements. This reality, motivated us to concentrate on tools, which could deal with such dynamic, disturbed scheduling problems, even though, due to the complexity of these problems, optimal solutions may not be possible to find.

Several attempts have been made to modify algorithms, to tune them for optimization in a changing environment. It was observed in manufacturing all these studies, that the dynamic environment requires an algorithm to maintain sufficient diversity for a continuous adaptation to the changes of the landscape. Although the interest in optimization algorithms for dynamic optimization problems is growing and a number of authors have proposed an even greater number of new approaches, the field lacks a general understanding as to suitable benchmark problems, fair comparisons and measurement of algorithm quality (Branke, 1999) (Cowling & Johanson, 2002) (Madureira, 2003), Madureira, Ramos & Silva, 2004) (Aytug, Lawley, McKay, Mohan & Uzsoy, 2005).

In spite of all the previous trials scheduling problem still known to be NP-complete. This fact incites researchers to explore new directions.

Hybrid Intelligent Systems

Hybridization of intelligent systems is a promising research field of computational intelligence focusing on combinations of multiple approaches to develop the next generation of intelligent systems. An important stimulus to the investigations on Hybrid Intelligent Systems area is the awareness that combined approaches will be necessary if the remaining tough problems in **artificial intelligence** are to be solved. Meta-Heuristics, Bio-Inspired Techniques, Neural computing, Machine Learning, Fuzzy Logic Systems, Evolution-

ary Algorithms, Agent-based Methods, among others, have been established and shown their strength and drawbacks. Recently, hybrid intelligent systems are getting popular due to their capabilities in handling several real world complexities involving imprecision, uncertainty and vagueness (Boeres, Lima, Vinod & Rebello, 2003), (Madureira, Ramos & Silva, 2004) (Bartz-Beielstein, Blesa, Blum, Naujoks, Roli, Rudolph & Sampels, 2007).

HYBRID META-HEURISTICS BASED SCHEDULING SYSTEM

The purpose of this article is to describe an framework based on combination of **Meta-Heuristics**, Tabu Search(TS) and Genetic Algorithms(GA), and constructive optimization methods for solving a class of real world scheduling problems, where the products (jobs) to be processed have due dates, release times and different assembly levels. This means that parts to be assembled may be manufactured in parallel, i.e. simultaneously.

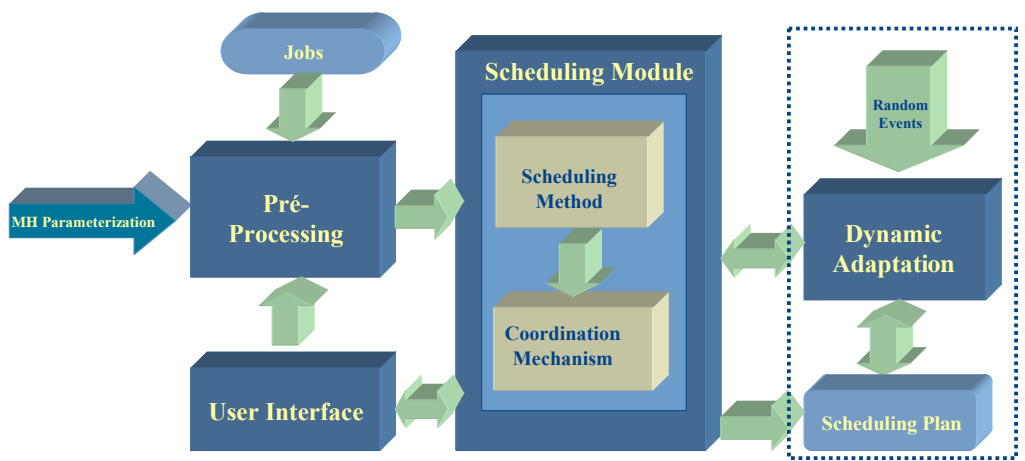

The problem, focused in this work, which we call Extended Job-Shop Scheduling Problem (EJSSP) has major extensions and differences in relation to the classic Job-Shop Scheduling Problem. In this work, we define a job as a manufacturing order for a final item, that could

be Simple or Complex. It may be Simple, like a part, requiring a set of operations to be processed. Complex Final Items, requiring processing of several operations on a number of parts followed by assembly operations at several stages, are also dealt with. Moreover, in practice, scheduling environment tends to be dynamic, i.e. new jobs arrive at unpredictable intervals, machines breakdown, jobs can be cancelled and due dates and processing times can change frequently (Madureira, 2003) (Madureira, Ramos & Silva, 2004).

It starts focusing on the solution of the dynamic deterministic EJSSP problems. For solving these we developed a framework, leading to a dynamic scheduling system having as a fundamental scheduling tool, a hybrid scheduling system, with two main pieces of intelligence (Figure 1).

One such piece is a combination of TS and GA based method and a mechanism for inter-machine activity coordination. The objective of this mechanism is to coordinate the operation of machines, taking into account the technological constraints of jobs, i.e. job operations precedence relationships, towards obtaining good schedules. The other piece is a **dynamic adaptation** module that includes mechanisms for neighbourhood/population regeneration under dynamic environments, increasing or decreasing it according new job arrivals or cancellations.

Figure 1. Hybrid meta-heuristics based scheduling system

A detailed description of the approach, methods and of its application to concrete problems can be found in Madureira (2003).

Pre-Processing Module

The pre-processing module deals with processing input information, namely problem definition and instantiation of algorithm components and parameters, such as, the initial solution and neighbourhood generation mechanisms, size of neighbourhood/population, tabu list attributes and tabu list length.

Hybrid Scheduling Module

Initially, we start by decomposing the deterministic EJSSP problem into a series of deterministic Single Machine Scheduling Problems (SMSP). We assume the existence of different and known job release times r_j , prior to which no processing of the job can be done and, also, job due dates d_j . Based on these, release dates and due dates are determined for each SMSP and, subsequently, each such problem is solved independently by a TS or a GA(considering a self-parameterization issue). Afterwards, the solutions obtained for each SMSP are integrated to obtain a solution to the main EJSSP problem instance.

The integration of the SMSP solutions may give an unfeasible schedule to the EJSSP. This is why schedule repairing may be necessary to obtain a feasible solution. The repairing mechanism named Inter-Machine Activity Coordination Mechanism (IMACM) carries this out. The repairing is based on coordination of machines activity, having into account job operation precedence and other problem constraints. This is done keeping job allocation order, in each machine, unchanged. The IMACM establishes the starting and the completion times for each operation. It ensures that the starting time for each operation is the higher of the two following values:

- the completion time of the immediately precedent operation in the job, if there is only one, or the highest of all if there are more;
- the completion time of the immediately precedent operation on the machine.

Dynamic Adaptation Module

For non-deterministic problems some or all parameters are uncertain, i.e. are not fixed as we assumed in the deterministic problem. Non-determinism of variables has to be taken into account in real world problems. For generating acceptable solutions in such circumstances our approach starts by generating a predictive schedule, using the available information and then, if perturbations occur in the system during execution, the schedule may have to be modified or revised accordingly, i.e. rescheduling/**dynamic adaptation** is performed. Therefore, in this process, an important decision must be taken, namely that of deciding if and when rescheduling should happen. The decision strategies for rescheduling may be grouped into three categories: continuous, periodic and hybrid rescheduling. In the continuous one rescheduling is done whenever an event modifying the state of the system occurs. In periodic rescheduling, the current schedule is modified at regular time intervals, taking into account the schedule perturbations that have occurred. Finally, for the hybrid rescheduling the current schedule is modified at regular time intervals if some perturbation occurs.

In the scheduling system for EJSSP, dynamic adaptation is necessary due to two classes of events:

- Partial events which imply variability in jobs or operations attributes such as processing times, due dates and release times.
- Total events which imply variability in neighbourhood structure, resulting from either new job arrivals or job cancellations.

While, on one hand, partial events only require redefining job attributes and re-evaluation of the objective function of solutions, total events, on the other hand, require a change on solution structure and size, carried out by inserting or deleting operations, and also re-evaluation of the objective function. Therefore, under a total event, the modification of the current solution is imperative. In this work, this is carried out by mechanisms described in (Madureira, Ramos & Silva, 2004) for SMSP.

Considering the processing times involved and the high frequency of perturbations, rescheduling all jobs from the beginning should be avoided. However, if

work has not yet started and time is available, then an obvious and simple approach to rescheduling would be to restart the scheduling from scratch with a new modified solution on which takes into account the perturbation, for example a new job arrival. When there is not enough time to reschedule from scratch or job processing has already started, a strategy must be used which adapts the current schedule having in consideration the kind of perturbation occurred.

The occurrence of a partial event requires redefinition of job attributes and a re-evaluation of the schedule objective function. A change in job due date requires the re-calculation of the operation starting and completion due times of all respective operations. However, changes in the operation processing times only requires re-calculation of the operation starting and completion due times of the succeeding operations. A new job arrival requires definition of the correspondent operation starting and completion times and a regenerating mechanism to integrate all operations on the respective single machine problems. In the presence of a job cancellation, the application of a regenerating mechanism eliminates the job operations from the SMSP where they appear. After the insertion or deletion of positions, neighbourhood regeneration is done by updating the size of the neighbourhood and ensuring a structure identical to the existing one. Then the scheduling module can apply the search process for better solutions with the new modified solution.

Job Arrival Integration Mechanism

When a new job arrives to be processed, an integration mechanism is needed. This analyses the job precedence graph that represents the ordered allocation of machines to each job operation, and integrates each operation into the respective single machine problem. Two alternative procedures could be used for each operation: either randomly select one position to insert the new operation into the current solution/chromosome or use some intelligent mechanism to insert this operation in the schedules, based on job priority, for example.

Job Elimination Mechanism

When a job is cancelled, an eliminating mechanism must be implemented so the correspondent position/gene will be deleted from the solutions.

Regeneration Mechanisms

After integration/elimination of operations is carried out, by inserting/deleting positions/genes in the current solution/chromosome, population regeneration is done by updating its size. The population size for SMSP is proportional to the number of operations.

After dynamic adaptation process, the scheduling method could be applied and search for better solutions with the modified solution.

In this way we proposed a hybrid system in which some self-organization aspects could be considered in accordance with the problem being solved: the method and/or parameters can change in run-time, the used MH can change according with problem characteristics, etc.

FUTURE TRENDS

Considering the complexity inherent to the manufacturing systems, the dynamic scheduling is considered an excellent candidate for the application of agent-based technology. A natural evolution to the approach above proposed is a Multi-agent Scheduling System that assumes the existence of several Machines Agents (which are decision-making entities) distributed inside the Manufacturing System that interact and cooperate with other agents in order to obtain optimal or near-optimal global performances.

The main idea is that from local, autonomous and often conflicting behaviours of the agents a global solution emerges from a community of machine agents solving locally their schedules and cooperating with other machine agents (Madureira, Gomes & Santos, 2006). Agents must be able to learn and manage their internal behaviours and their relationships with other agents, by **cooperative** negotiation in accordance with business policies defined by user manager. Some self-organization aspects could be considered in accordance with the problem being solved: the method and/or parameters can change in run-time, the agents can use different MH according with problem characteristics, etc.

CONCLUSION

This article proposes a system architecture that makes good use and combination of the advantages of two different Meta-Heuristics: Tabu Search and Genetic Algorithms.

We believe that a new contribution for the resolution of more realistic scheduling problems, the Extended Job-Shop Problems was described. The particularity of our approach is the procedure to schedule operations, as each machine will first find local optimal or near optimal solutions, succeeded by the interaction with other machines through cooperation mechanisms as a way to find an optimal global schedule, on dynamic environments.

The proposed system is prepared to use other Local Search Meta-Heuristics, to drive schedules based on practically any performance measure and it is not restricted to a specific type of scheduling problems.

KEY TERMS

Cooperation: The practice of individuals or entities working together with common goals, instead of working separately in competition, and in which the success of one is dependent and contingent upon the success of the other.

Dynamic Scheduling Systems: Are frequently subject to several kinds of random occurrences and perturbations, such as new job arrivals, machine breakdowns, employee's sickness, jobs cancellation and due date and time processing changes, causing prepared schedules becoming easily outdated and unsuitable.

Evolutionary Computation: A subfield of artificial intelligence that involve techniques implementing mechanisms inspired by biological evolution such as reproduction, mutation, recombination, natural selection and survival of the fittest.

Genetic Algorithms: Particular class of evolutionary algorithms that use techniques inspired by evolutionary biology such as inheritance, mutation, selection, and crossover.

Hybrid Intelligent Systems: Denotes a software system which employs, a combination of Artificial Intelligence models, methods and techniques, such as Evolutionary Computation, Meta-Heuristics, Multi-Agent Systems, Expert Systems and others.

Meta-Heuristics: Form a class of powerful and practical solution techniques for tackling complex, large-scale combinatorial problems producing efficiently high-quality solutions.

Multi-Agent Systems: A system composed of several agents, collectively capable of solve complex problems in a distributed fashion without the need for each agent to know about the whole problem being solved.

Scheduling: Can be seen as a decision making process for operations starting and resources to be used. A variety of characteristics and constraints related with jobs and machine environments (Single Machine, Parallel machines, Flow-Shop and Job-Shop) can affect scheduling decisions.

Tabu Search: A approximation method, belonging to the class of local search techniques, that enhances the performance of a local search method by using memory structures (Tabu List).

A Hybrid System for Automatic Infant Cry Recognition I

INTRODUCTION

Crying in babies is a primary communication function, governed directly by the brain; any alteration on the normal functioning of the babies' body is reflected in the cry (Wasz-Höckert, *et al*, 1968). Based on the information contained in the cry's wave, the infant's physical state can be determined; and even pathologies in very early stages of life detected (Wasz-Höckert, *et al*, 1970).

To perform this detection, a Fuzzy Relational Neural Network (FRNN) is applied. The input features are represented by fuzzy membership functions and the links between nodes, instead of weights, are represented by fuzzy relations (Reyes, 1994). This paper, as the first of a two parts document, describes the Infant Cry Recognition System's architecture as well as the FRNN model. Implementation and testing are reported in the complementary paper.

BACKGROUND

The pioneer works on infant cry were initiated by Wasz-Höckert since the beginnings of the 60's. In one of those works his research group showed that the four basic types of cry can be identified by listening: pain, hunger, pleasure and birth. Further studies led to the development of conceptual models that describe the anatomical and physiologic basis of the production and neurological control of crying (Bosma, Truby & Antolop, 1965). Later on, Wasz-Höckert (1970) applied

spectral analysis to identify several types of crying. Other works showed that there exist significant differences among the several types of crying, like healthy infant's cry, pain cry and pathological infant's cry. In one study, Petroni used Neural Networks (Petroni, Malowany, Johnston, and Stevens, 1995) to differentiate between pain and no-pain crying. Cano directed several works devoted to the extraction and automatic classification of acoustic characteristics of infant cry. In one of those studies, in 1999 Cano presented a work where he demonstrates the utility of the Kohonen's Self-Organizing Maps in the classification of Infant Cry Units (Cano-Ortiz, Escobedo-Becerro, 1999) (Cano, Escobedo and Coello, 1999). More recently, in (Orozco, & Reyes, 2003) we reported the classification of cry samples from deaf and normal babies with feed-forward neural networks. In 2004 Cano and his group, in (Cano, Escobedo, Ekkel, 2004) reported a radial basis network (RBN) to find out relevant aspects concerned with the presence of Central Nervous System (CNS) diseases. In (Suaste, Reyes, Diaz, and Reyes, 2004) we showed the implementation of a Fuzzy Relational Neural Network (FRNN) for Detecting Pathologies by Infant Cry Recognition.

The study of connectionist models also known as Artificial Neural Networks (ANN) has enjoyed a resurgence of interest after its demise in the 60's. Research was focused on evaluating new neural networks for pattern classification, training algorithms using real speech data, and on determining whether parallel neural network architectures can be designed to perform efficiently the work required by complex

speech recognition algorithms (Lippmann, 1990). In the connectionist approach, pattern classification is done with a multi-layer neural network. A weight is assigned to every link between neurons in contiguous layers. In the input layer each neuron receives one of the features present in the input pattern vectors. Each neuron in the output layer corresponds to each speech unit class (word or sub-word). The neural network associates input patterns to output classes by modeling the relationship between the two pattern sets. The pattern is estimated or learned by the network with a representative sample of input and output patterns (Morgan, and Scofield, 1991) (Pedrycz, 1991).. In order to stabilize the perceptron's behavior, many researchers had been trying to incorporate fuzzy set theory into neural networks. The theory of fuzzy sets, developed by Zadeh in 1965 (Zadeh, 1965), has since been used to generalize existing techniques and to develop new algorithms in pattern recognition. Pal (Pal, 1992a) suggested that to enable systems to handle real-life situations, fuzzy sets should be incorporated into neural networks, and, that the increase in the amount of computation required with its incorporation, is offset by the potential for parallel computation with high flexibility that fuzzy neural networks have. Pal proposes how to do data fuzzification, the general

system architecture of a fuzzy neural network and the use of 3n-dimensional vectors to represent the fuzzy membership values of the input features to the primary linguistic properties *low*, *medium*, and *high* (Pal, 1992a) and (Pal, and Mandal, 1992b). On the other side, the idea of using a relational neural network as a pattern classifier was developed by Pedrycz and presented in (Pedrycz, 1991). As a result of the combination of the Pal's and Pedrycz's proposed methodologies in 1994 C. A. Reyes (1994) developed the hybrid model known as fuzzy relational neural network (FRNN).

THE AUTOMATIC INFANT CRY RECOGNITION PROCESS

The infant cry automatic classification process is, in general, a pattern recognition problem, similar to Automatic Speech Recognition (ASR) (Huang, Acero, Hon, 2001). The goal is to take the wave from the infant's cry as the input pattern, and at the end obtain the kind of cry or pathology detected on the baby (Cano, Escobedo and Coello, 1999) (Ekkel, 2002). Generally, the process of Automatic Infant Cry Recognition is done in two steps. The first step is known as signal processing, or feature extraction, whereas the second is known as

Figure 1. Automatic infant cry recognition process

pattern classification. In the acoustical analysis phase, the cry signal is first normalized and cleaned, and then it is analyzed to extract the most important features in function of time. The set of obtained features is represented by a vector, which represents a pattern. The set of all vectors is then used to train the classifier. Later on, a set of unknown feature vectors is compared with the acquired knowledge to measure the classification output efficiency. Figure 1 shows the different stages of the described recognition process.

Cry Patterns Classification

The vectors, representing patterns, obtained in the extraction stage are later used in the classification process. There are four basic schools for the solution of the pattern classification problem, those are: *a)* Pattern comparison (dynamic programming), *b)* Statistic Models (Hidden Markov Models HMM), *c)* Knowledge based systems (expert systems), and *d)* Connectionists Models (neural networks). In recent years, a new strong trend of more robust hybrid classifiers has been emerging. Some of the better known hybrid models result from the combination of neural and fuzzy approaches (Jang, 1993) (Lin Chin-Teng, and George Lee, 1996). For the work shown here, we have implemented a hybrid model of this type, called the Fuzzy Relational Neural Network, whose parameters are found through the application of genetic algorithms. We selected this kind of model, because of its adaptation, learning and knowledge representation capabilities. Besides, one of its main functions is to perform pattern recognition.

In an Automatic Infant Cry Classification System, the goal is to identify a model of an unknown pattern obtained after the original sound wave is acoustically analyzed, and its dimensionality reduced. So, in this phase we determine the class or category to which each cry pattern belongs to. The collection of samples, each of which is represented by a vector of n features, is divided in two subsets: The training set and the test set. First, the training set is used to teach the classifier to distinguish between the different crying types. Then the test set is used to determine how well the classifier assigns the corresponding class to a pattern by means of the classification scheme generated during training.

THE FUZZY NEURAL NETWORK MODEL

The system proposed in this work is based upon fuzzy set operations in both; the neural network's structure and the learning process. Following Pal's idea of a general recognizer (Pal, S.K., 1992a), the model is divided in two main parts, one for learning and another for processing, as shown in Figure 2.

Fuzzy Learning

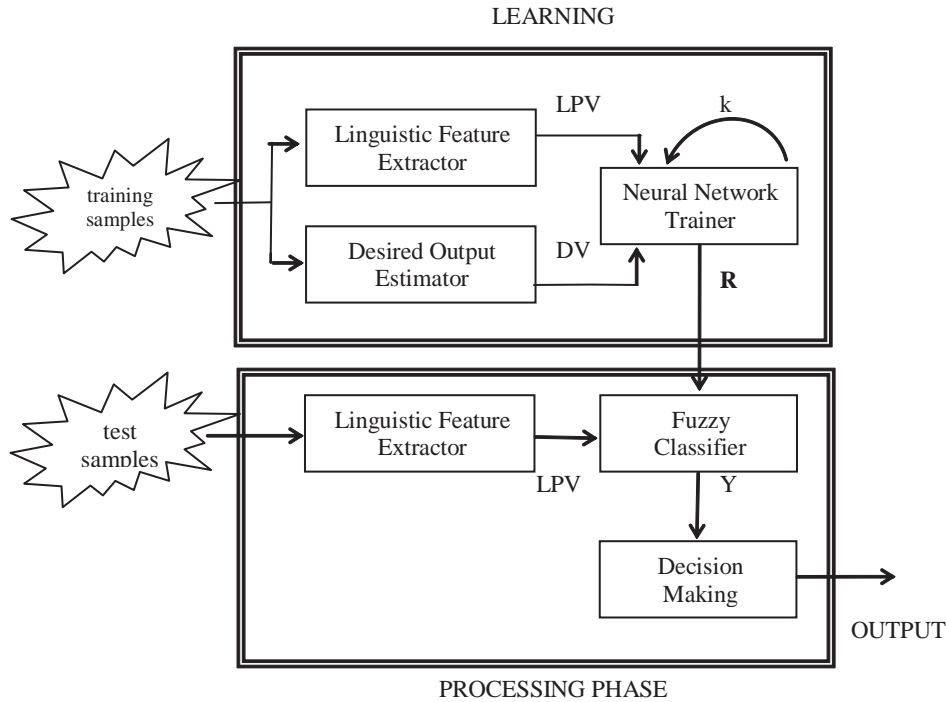

The fuzzy learning section is composed by three modules, namely the Linguistic Feature Extractor (LFE), the Desired Output Estimator (DOE), and the Neural Network Trainer (NNT). The Linguistic Feature Extractor takes training samples in the form of n -dimensional vectors containing n features, and converts them to Nn -dimensional form vectors, where N is the number of linguistic properties. In this case the linguistic properties are *low*, *medium*, and *high*. The resulting $3n$ -dimensional vector is called Linguistic Properties Vector (LPV). In this way an input pattern $F_i = [F_{i1}, F_{i2}, \dots, F_{in}]$ containing n features, may be represented as (Pal, and Mandal, 1992b)

$$F_i = [\mu_{low(F_{i1})}(F_{i1}), \mu_{med(F_{i1})}(F_{i1}), \mu_{high(F_{i1})}(F_{i1}), \dots, \mu_{low(F_{in})}(F_{in}), \mu_{med(F_{in})}(F_{in}), \mu_{high(F_{in})}(F_{in})]$$

The DOE takes each vector from the training samples and calculates its membership to class k , in an l -class problem domain. The vector containing the class membership values is called the Desired Vector (DV). Both LPV and DV vectors are used by the neural Network Trainer (NNT), which takes them for training the network.

The neural network has only one input and one output layer. The input layer is formed by a set of Nn neurons, with each of them corresponding to one of the linguistic properties assigned to the n input features. In the output layer there are l neurons, with each node corresponding to one of the l classes; in this implementation, each class represents one type of crying. There is a link from every node in the input layer to every node in the output layer. All the con-

Figure 2. General architecture of the automatic infant cry recognition system

nections are described by means of fuzzy relations $R: X \times Y \rightarrow [0, 1]$ between the input and output nodes. The error is represented by the distance between the actual output and the target or desired output. During each learning step, once the error has been computed, the trainer adjusts the relationship values or weights of the corresponding connections, either until a minimum error is obtained or a given number of iterations are completed. The output of the NNT, after the learning process, is a fuzzy relational matrix (R in Figure 1) containing the knowledge needed to further map the unknown input vectors to their corresponding class during the classification process.

Fuzzy Processing

The fuzzy processing section is formed by three different modules, namely the Linguistic Feature Extractor (LFE), the Fuzzy Classifier (FC), and the Decision Making Module (DMM). The LFE works as the one in

the learning phase, described in the previous section. The output of this module is an LPV vector, which along with the fuzzy relational matrix R , are used by the Fuzzy Classifier, which obtains the actual outputs from the neural network. The classifier applies the max-min composition to calculate the output. The output of this module is an output vector containing the membership values of the input vector to each of the classes. Finally, the Decision Making module selects the highest value from the classifier and assigns the corresponding class to the testing vector.

Membership Functions

A membership function maps values in a domain to their membership value in a fuzzy set. Several kinds of membership functions are available. In the reported experiments triangular membership functions were used. According to (Park, Cae, and Kandel, 1992) the use of more linguistic properties to describe a pattern

point makes a model more accurate, but too many can make the description unpractical. So, here we use seven linguistic properties: *very low, low, more or less low, medium, more or less high, high, and very high*.

Desired Membership Values

Before defining the output membership function, we define the equation to calculate the weighted distance of the training pattern F_j to the k th class in an l -class problem domain as in (Pal, 1992a)

$$z_{ik} = \sqrt{\sum_{j=1}^n \left[\frac{F_{ij} - \sigma_{kj}}{v_{kj}} \right]^2}, \text{ for } k = 1, \dots, l$$

where F_{ij} is the j th feature of the i th pattern vector, σ_{kj} denotes the mean, and v_{kj} denotes the standard deviation of the j th feature for the k th class. The membership value of the i th pattern to class k is defined as follows

$$\mu_k(F_i) = \frac{1}{1 + \left(\frac{z_{ik}}{f_d} \right)^{f_e}}, \text{ } \mu_k(F_i) \in [0, 1]$$

where f_e is the exponential fuzzy generator, and f_d is the denominational fuzzy generator controlling the amount of fuzziness in this class-membership set. In this case, the higher the distance of the pattern from a class, the lower its membership to that class. Since the training data have fuzzy class boundaries, a pattern point usually belongs to more than one class at different degrees.

The Neural Network Trainer

The neural network model discussed here is based on the relational neural structure proposed by Pedrycz in (Pedrycz, W., 1991).

The Relational Neural Network (RNN): Let $\mathbf{X} = \{x_1, x_2, \dots, x_n\}$ be a finite set of input nodes and let $\mathbf{Y} = \{y_1, y_2, \dots, y_l\}$ represent the output nodes set in an l -class problem domain. When the *max-min* composition operator denoted $X \circ R$ is applied to a fuzzy set X and a fuzzy relation R , the output is a new fuzzy set Y , we have

$$Y = X \circ R$$

$$Y(y_j) = \max_{x_i} \left(\min \left(X(x_i), R(x_i, y_j) \right) \right) \quad (1)$$

where X is a fuzzy set, Y is the resulting fuzzy set and R a fuzzy relation $R : X \times Y \rightarrow [0, 1]$ describing all relationships between input and output nodes. We will take the whole neural network represented by expression (1) as a collection of l separate n -input single-output cells.

Learning in a Fuzzy Neural Network: If the actual response from the network does not match the target pattern; the network is corrected by modifying the link weights to reduce the difference between the observed and target patterns. To measure the difference a performance index called equality index is defined, which is

$$T(y) \equiv Y(y) = \begin{cases} 1 + T(y) - Y(y), & \text{if } Y(y) > T(y) \\ 1 + Y(y) - T(y), & \text{if } Y(y) < T(y) \\ 1, & \text{if } Y(y) = T(y) \end{cases}$$

where $T(y)$ is the target output at node y , and $Y(y)$ is the actual output at the same node. In a problem with n input patterns, there are n input-output pairs (x_{ij}, t_i) where t_i is the target value when the input is X_{ij} .

Parameters Updating: Pedrycz also proposes to complete the process of learning separately for each output node. The learning algorithm is a version of the back-propagation algorithm. Let's consider an n -input- L -output neural network having the following form

$$y_i = f(x_i; \mathbf{a}, \mathbf{v}) = \left(\bigvee_{j=1}^n (a_j \wedge x_{ij}) \right)$$

where $\mathbf{a} = [a_1, a_2, \dots, a_L]$ is a vector containing all the weights or relations, $\mathbf{x}_i = [x_{i1}, x_{i2}, \dots, x_{in}]$ is the vector with the values observed in the input nodes. The parameters a and v are updated iteratively by taking increment Δa_m resulting from deviations between all pairs y_i and t_i as follows

$$a(k+1) = a(k) + \Psi_1(k) \left[\frac{\Delta a(k+1)}{Nn} + \eta \frac{\Delta a(k)}{Nn} \right]$$

where k is the learning step. Ψ_1 and Ψ_2 are non-increasing functions of k controlling the decreasing influence of increments Δa_m . Ψ is the learning momentum

specifying the level of modification of the learning parameters with regard to their values in the previous learning step k . A way of determining the increments Δa_m is with regard to the m th coordinates of a , $m = 1, 2, \dots, L$. The computation of the overall performance index, and the derivatives to calculate the increments for each coordinate of a , and v are explained in detail in (Reyes, C. A., 1994). Once the training has been terminated, the output of the trainer is the updated relational matrix, which will contain the knowledge needed to map unknown patterns to their corresponding classes.

FUTURE TRENDS

One unexplored possibility of improving the FRNN performance is the use of other fuzzy relational products instead of max-min composition. Moreover, membership functions have parameters which can be optimized by genetic algorithms any other optimizing technique. Adequate parameters may improve learning and recognition efficiency of the FRNN.

CONCLUSIONS

We have presented the development and implementation of an AICR system as well as a powerful hybrid classifier, the FRNN, which is a model formed by the combination of fuzzy relations and artificial neural networks. The synergistic symbiosis obtained through the fusion of both methodologies will be demonstrated. In the related paper on applications of this model, we will show some practical results, as well as an improved model by means of genetic algorithms.

KEY TERMS

Artificial Neural Networks: A network of many simple processors that imitates a biological neural network. The units are connected by unidirectional communication channels, which carry numeric data. Neural networks can be trained to find nonlinear relationships in data, and are used in applications such as robotics, speech recognition, signal processing or medical diagnosis.

Automatic Infant Cry Recognition (AICR): A process where the crying signal is automatically analyzed, to extract acoustical features looking to determine the infant's physical state, the cause of crying or even detect pathologies in very early stages of life.

Back propagation Algorithm: Learning algorithm of ANNs, based on minimising the error obtained from the comparison between the outputs that the network gives after the application of a set of network inputs and the outputs it should give (the desired outputs).

Fuzzy Relational Neural Network (FRNN): A hybrid classification model combining the advantages of fuzzy relations with artificial neural networks.

Fuzzy Sets: A generalization of ordinary sets by allowing a degree of membership for their elements. This theory was proposed by Lofti Zadeh in 1965. Fuzzy sets are the base of fuzzy logic.

Hybrid Intelligent System: A software system which employs, in parallel, a combination of methods and techniques from Soft Computing.

Learning Stage: A process to teach classifiers to distinguish between different pattern types.

A Hybrid System for Automatic Infant Cry Recognition II

INTRODUCTION

Automatic Infant Cry Recognition (AICR) process is basically a problem of pattern processing, very similar to the Automatic Speech Recognition (ASR) process (Huang, Acero, Hon, 2001). In AICR first we perform acoustical analysis, where the crying signal is analyzed to extract the more important acoustical features, like; LPC, MFCC, etc. (Cano, Escobedo and Coello, 1999). The obtained characteristics are represented by feature vectors, and each vector represents a pattern. These patterns are then classified in their corresponding pathology (Ekkel, 2002). In the reported case we are automatically classifying cries from normal, deaf and asphyxiating infants.

We use a genetic algorithm to find several optimal parameters needed by the Fuzzy Relational Neural Network FRNN (Reyes, 1994), like; the number of linguistic properties, the type of membership function, the method to calculate the output and the learning rate. The whole model has been tested on several data sets for infant cry classification. The process, as well as some results, is described.

BACKGROUND

In the first part of this document a complete description of the AICR system as well as of the FRNN is given. So, with continuity purposes, in this part we will concentrate in the description of the genetic algorithm and the whole system implementation and testing.

A genetic algorithm refers to a model introduced and investigated by John Holland (John Holland, 1975) and by students of Holland (DeJong, 1975). Genetic algorithms are often viewed as function optimizers, although the range of problems to which genetic algorithms have been applied is quite broad. Recently, numerous papers and applications combining fuzzy concepts and genetic algorithms (GAs) have become known, and there is an increasing concern in the integration of these two topics. In particular, there are a great number of publications exploring the use of GAs for developing or improving fuzzy systems, called genetic fuzzy systems (GFSSs) (Cordon, Oscar, *et al*, 2001) (Casillas, Cordon, del Jesus, Herrera, 2000).

EVOLUTIONARY DESIGN

Within the evolutionary techniques, perhaps one of the most popular is the genetic algorithm (AG) (Goldberg, 1989). Its structure presents analogies with the biological theory of evolution, and is based on the principle of the survival of the fittest individual (Holland, 1975). Generally, a genetic algorithm has five basic components (Michalewicz, 1992). A representation of potential solutions to the problem, a form to create potential initial solutions, a fitness function that is in charge to evaluate solutions, genetic operators that alter the offspring's composition, and values for parameters like the size of the population, crossover probability, mutation probability, number of generations and others. Here we present different features of the genetic

algorithm used to find a combination of parameters for the FRNN.

Chromosomal Representation

The binary codification is used in genetic algorithms, and Holland in (Holland, 1975) gave a theoretical justification to use it. Holland argued that the binary codification allows having more schemes than a decimal representation. Scheme is a template that describes a subgroup of strings that share certain similarities in some positions throughout their length (Goldberg, 1989). The problem variables consist of the number of linguistic properties, the type of membership function, the classification method and the learning rate. We are interested in having between 3 and 7 linguistic properties, so, the number of linguistic variables is encoded into a binary string of 3 bit length. The membership function is represented as a 2 bit string, where [00] decodes the Trapezoidal membership function, [01] decodes the Π function, [10] decodes the Triangular function, [11] decodes the Gaussian membership function. The classification methods are also coded as a 2 bit string, where [00] represents the max-min composition, [01] represents the geometrical mean and [10] represents the relational square product. Finally, the learning rate is represented as a binary string of 3 bit length, where [000] decodes to 0.1 learning rate, [001] decodes to 0.2 learning rate, [010] decodes to 0.31 learning rate, [011] decodes to 0.4 learning rate, and [100] decodes to 0.5 learning rate. A larger learning rate is not desirable, so all other bit values are ignored. The chromosome is obtained by concatenating all the above strings. Figure 1 shows an example of the chromosomal representation. Initial population is generated from a random selection of chromosomes, a population size of 50 was considered.

Genetic Operations

We use four genetic operations, namely elitism, roulette wheel selection, crossover and mutation. **Elitism:** In order to ensure that the members with highest fitness value of the population stay in the next generation we apply elitism. It has been demonstrated (Günter, Rudolph, 1994), that a genetic algorithm must use elitism to be able to show convergence. At each iteration of the genetic algorithm we select the members with the four highest fitness values and we put them in the next generation.

Selection: In the genetic algorithm the selection process is made in a probabilistic way, it is to say, the less apt individuals even have a certain opportunity to be selected. There are many different types of selection approaches; we use the roulette wheel selection, where members of the population have a probability of being selected that is directly proportionate to their fitness. **Crossover:** In this work we use a single point crossover. Observing the performance of different crossover operators, De Jong (De Jong, K., 1975) concluded that, although increasing the number of points of crosses affects its schemes from a theoretical perspective, in practice this does not seem to have a significant impact. The crossover is the principal operator in the genetic algorithm. Based on some experiments we decided to determine the crossover point randomly and the crossover probability was fixed at 0.8. **Mutation:** This operator allows the introduction of new chromosomal material in the population. We selected a gene randomly and we replaced it by its complement, a zero is changed by a one and a one is changed by a zero. Some authors suggest that the mutation probability equal to $1/L$, where L is the length of the chain of bits is an inferior limit acceptable for the optimal percentage of mutation (Bäck, Thomas, 1993). In this work the mutation probability is fixed at 0.05.

Fitness Function

The objective function of our optimization problem is called fitness function. This function must be able to penalize the solutions that are not good and award the good ones so they can propagate quickly (Coello, Carlos A., 1995). As a fitness function we use the classification error given by the Fuzzy Relational Neural Network. Then the fitness function is defined by the following equation

$$F = e_{FRNN}$$

In this case we define the classification error as follows

$$e_{FRNN} = \frac{No.PM}{No.S}$$

where *No.PM* represents the number of perfect matches, in other words, it represents the number of samples classified correctly. The term *No.S* represents the total number of given samples to the FC.

IMPLEMENTATION AND RESULTS

Signal Processing

The analysis of the raw cry waveform provides the information needed for its recognition. At the same time, it discards unwanted information such as background noise, and channel distortion (Levinson S.E., and Roe, D.B., 1990). Acoustic feature extraction is a transformation of measured data into pattern data. Some of the most important techniques used for analyzing cry wave signals are: Discrete Fourier Transform (DFT), cepstral processing, and Linear Prediction Analysis (LPA) (Ainsworth, W.A., 1988) (Schafer and Rabiner 1990). The application of these techniques during signal processing obtains the values of a set of acoustic features. The features may be spectral coefficients, linear prediction coefficients (LPC), Mel frequency cepstral coefficients (MFCC), among others (Ainsworth, W.A., 1988). The set of values for *n* features may be repre-

sented by a vector in an *n*-dimensional space. Each vector represents a pattern.

For the present experiments we work with samples of infant cries. The infant cries were collected by recordings done directly by medical doctors and then, each signal wave was divided in segments of 1 second, each segment represents a sample. Then, acoustic features were obtained by means of techniques as Linear Prediction Coefficients (LPC) and Mel Frequency Cepstral Coefficients (MFCC), by the use of the freeware program Praat v4.0.8 (Boersma, P., Weenink, 2002). Every sample of 1 second is divided in frames of 50-milliseconds and from each frame we extract 16 coefficients, this procedure generates vectors with 304 coefficients by sample. In this paper we show the results obtained with Mel Frequency Cepstral Coefficients.

In order to reduce the dimensions of the sample vectors we apply Principal Component Analysis. The FRNN and the genetic algorithm are implemented in Matlab. We have a corpus of 157 samples of normal infant cry, 340 of asphyxia infant cry, and 879 of hypo acoustics. Also we have a corpus of 192 samples of pain and 350 samples of hunger crying. We worked with a population of 50 individuals and the number of training epochs for the FRNN was set at three. The initial population was randomly chosen. The number of generations needed for the genetic algorithm was of only three. These values were set on the basis of the observation of the results of several experiments.

Preliminary Results

Three different classification experiments were made, the first one consists in classifying deaf and normal infant cry, the second one was made to classify infant cry in categories called asphyxia and normal, and the third one to classify hunger and pain crying. In each task the training samples and the test samples are randomly selected. The results of the model in the classification of deaf and normal cry are given in Table I. In Table II we show the results obtained in the second classification task. Finally Table III shows the results in the classification of hunger and pain cry. In every classification task the GA was run about 15 times and the reported results show the average of the best classification in each experiment.

Table 1. Results of classifying deaf and normal cry

| Characteristics | Successful codification | Interpretation | Accuracy |
|---------------------------------|-------------------------|----------------|----------|
| Number of linguistic properties | 0 1 1 | 3 | 98% |
| Membership function | 0 1 | II | |
| Classification method | 0 0 | max-min | |
| Learning rate | 0 0 1 | 0.2 | |

Table 2. Results of classifying asphyxia and normal cry

| Characteristics | Successful codification | Interpretation | Accuracy |
|---------------------------------|-------------------------|------------------|----------|
| Number of linguistic properties | 0 1 1 | 3 | 84% |
| Membership function | 0 1 | II | |
| Classification method | 0 1 | geometrical mean | |
| Learning rate | 0 10 | 0.31 | |

Table 3. Results of classifying hunger and pain cry

| Characteristics | Successful codification | Interpretation | Accuracy |
|---------------------------------|-------------------------|----------------|----------|
| Number of linguistic properties | 1 1 1 | 7 | 95.24% |
| Membership function | 0 1 | II | |
| Classification method | 0 0 | max-min | |
| Learning rate | 0 1 0 | 0.31 | |

Performance Comparison with Other Models

Reyes and Orozco (Orozco, Reyes, 2003) classified cry samples from deaf and normal babies, obtaining recognition results around 97.43%. Reyes *et al* (Suaste, Reyes, Diaz, Reyes, 2004) showed an implementation of a linguistic fuzzy relational neural network to classify normal and pathological infant cry with percentage of correct classification of 97.3% and 98%. Petroni, Malowany, Johnston and Stevens (1995) classified cry from normal babies to identify pain with artificial neural networks and report results of correct classification that go from 61% with cascade-correlation networks up to 86.2% with feed-forward neural networks. In (Lederman, 2002) Dror Lederman presents some classification results for infants with respiratory distress syndrome RDS (related to asphyxia) versus healthy infants. For the classification he used a Hidden Markov Model architecture with 8 states and 5 Gaussians/state. The results reported are of 63 % of total mean correct classification.

FUTURE TRENDS

AICR systems may expand their utility by training them to recognize a larger number of pathologies. The first requirement to achieve this goal is to collect a suitable set of labeled samples for any target pathology. The GA presented here optimizes some parameters of the FRNN, but the model has more. So, other parameters can be added to the chromosomal representation in order to improve the model, like initial values of the relational matrix and of the bias vectors, number of training epochs, and the values of the exponential fuzzy generator and the denominational fuzzy generator used by the DOE.

CONCLUSIONS

The proposed genetic algorithm computes a selection of the number of linguistic properties, the membership function used to calculate the linguistic features, the method to calculate the output of the classifier in the fuzzy processing section and the learning rate of the FRNN. The solution obtained by the proposed genetic algorithm is a set of characteristics that the FRNN can

use to make the classification of infant cry. The use of linguistic properties allows us to deal with the impreciseness of infant cry and provides the classifier with very useful information. By applying the linguistic information and given the nature of the model, it is not necessary to get training through a high number of learning epochs, a high number of iterations in the genetic algorithm is not necessary either. The results of classifying deaf and normal infant cry are very similar to other models, but when we classify hunger and pain the results are much better than other models.

KEY TERMS

Binary Chromosome: Is an encoding scheme representing one potential solution to a problem, during a searching process, by means of a string of bits.

Evolutionary Computation: A subfield of computational intelligence that involves combinatorial optimization problems. It uses iterative progress, such as growth or development in a population, which is then selected in a guided random search to achieve the desired end. Such processes are often inspired by biological mechanisms of evolution.

Fitness Function: It is a function defined over the genetic representation and measures the *quality* of the represented solution. The fitness function is always problem dependent.

Genetic Algorithms: A family of computational models inspired by evolution. These algorithms encode a potential solution to a specific problem on a simple chromosome-like data structure and apply recombination operators to these structures so as to preserve critical information. Genetic algorithms are often viewed as function optimizers, although the range of problems to which genetic algorithms have been applied is quite broad.

Hybrid Intelligent System: A software system which employs, in parallel, a combination of methods and techniques mainly from subfields of Soft Computing.

Signal Processing: The analysis, interpretation and manipulation of signals. Processing of such signals includes storage and reconstruction, separation of information from noise, compression, and feature extraction.

Soft Computing: A partnership of techniques which in combination are tolerant of imprecision, uncertainty, partial truth, and approximation, and whose role model is the human mind. Its principal constituents are Fuzzy Logic (FL), Neural Computing (NC), Evolutionary Computation (EC) Machine Learning (ML) and Probabilistic Reasoning (PR).

IA Algorithm Acceleration Using GPUs

Antonio Seoane

University of A Coruña, Spain

Alberto Jaspe

University of A Coruña, Spain

INTRODUCTION

Graphics Processing Units (GPUs) have been evolving very fast, turning into high performance programmable processors. Though GPUs have been designed to compute graphics algorithms, their power and flexibility makes them a very attractive platform for general-purpose computing. In the last years they have been used to accelerate calculations in physics, computer vision, artificial intelligence, database operations, etc. (Owens, 2007).

In this paper an approach to general purpose computing with GPUs is made, followed by a description of artificial intelligence algorithms based on Artificial Neural Networks (ANN) and Evolutionary Computation (EC) accelerated using GPU.

BACKGROUND

General-Purpose Computation using Graphics Processing Units (GPGPU) consists in the use of the GPU as an alternative platform for parallel computing taking advantage of the powerful performance provided by the graphics processor (*General-Purpose Computation Using Graphics Hardware Website*; Owens, 2007).

There are several reasons that justify the use of the GPU to do general-purpose computing (Luebke, 2006):

- Last generation GPUs are very fast in comparison with current processors. For instance, a NVIDIA 8800 GTX card has computing capability of approximately 330 GFLOPS, whereas an Intel Core2 Duo 3.0 GHz processor has only a capability of about 48 GFLOPS.
- GPUs are highly-programmable. In the last years graphical chip programming capacities have grown very much, replacing fixed-programming

engines with programmable ones, like pixel and vertex engines. Moreover, this has derived in the appearance of high-level languages that help its programming.

- GPUs evolution is faster than CPU's one. The increase in GPU's performance is nowadays from 1.7x to 2.3x per year, whereas in CPUs is about 1.4x. The pressure exerted by videogame market is one of the main reasons of this evolution, what forces companies to evolve graphics hardware continuously.
- GPUs use high-precision data types. Although in the very beginning graphics hardware was designed to work with low-precision data types, at the present time internal calculations are computed using 32 bits float point numbers.
- Graphics cards have low cost in relation to the capacities that they provide. Nowadays, GPUs are affordable for any user.
- GPUs are highly-parallel and they can have multiple processors that allow making high-performance parallel arithmetic calculations.

Nevertheless, there are some obstacles. First, not all the algorithms fit for the GPU's programming model, because GPUs are designed to compute high-intensive parallel algorithms (Harris, 2005). Second, there are difficulties in using GPUs, due mainly to:

- GPU's programming model is different from CPU's one.
- GPUs are designed to graphics algorithms, therefore, to graphics programming. The implementation of general-purpose algorithms on GPU is quite different to traditional implementations.
- Some limitations or restrictions exist in programming capacities. Most functions on GPU's programming languages are very specific and dedicated to make calculations in graphics algorithms.

- GPU's architectures are quite variable due to their fast evolution and the incorporation of new features.

Therefore it is not easy to port an algorithm developed for CPUs to run in a GPU.

Overview of the Graphics Pipeline

Nowadays GPUs make their computations following a common structure called *Graphics Pipeline*. The Graphics Pipeline (Akenine-Möller, 2002) is composed by a set of stages that are executed sequentially inside the GPU, allowing the computing of graphics algorithms. Recent hardware is made up of four main elements. First, the *vertex processors*, that receive vertex arrays from CPU and make the necessary transformations from their positions in space to the final position in the screen. Second, the *primitive assembly* build graphics primitives (for instance, triangles) using information about connectivity between different vertex. Third, in the *rasterizer*, those graphical primitives are discretized and turned into fragments. A fragment represents a potential pixel and contains the necessary information (color, depth, etc.) to generate the final color of a pixel. Finally, in the *fragment processors*, fragments become pixels to which final color is written in a target buffer, that can be the screen buffer or a texture.

In the present, GPUs have multiple vertex and fragment processors that compute operations in parallel. Both are programmable using little pieces of code called vertex and fragment programs, respectively. In the last years different high-level programming languages have released like Cg/HLSL (Mark, 2003; HLSL Shaders) or GLSL (*OpenGL Shading Language Information Site*), that make easier the programming of those processors.

The GPU Programming Model

There is a big difference between programming CPUs and GPUs due mainly to their different programming models. GPUs are based on the *stream programming model* (Owens, 2005a; Luebke, 2006; Owens, 2007), where all data are represented by a *stream* that can be defined as a sorted set of data of the same type. A *kernel* operates on full streams, and takes input data from one or more streams to produce one or more output streams. The main characteristic of a kernel is

that it operates on the whole stream, instead individual elements. The typical use of a kernel is the evaluation of a function over each element from an input stream, calling this a *map* operation. Other operations of a kernel are expansions, reductions, filters, etc. (Buck, 2004; Horn, 2005; Owens, 2007). The kernel generated outputs are always based on their input streams, what means that inside the kernel, the calculations made on an element never depends of the other ones. In stream programming model, applications are built connecting multiple kernels. An application can be represented as a dependency graph where each graph node is a kernel and each edge represents a data stream between kernels (Owens, 2005b; Lefohn, 2005).

The behavior of graphic pipeline is similar to the stream programming model. Data flows through each stage, where the output feeds the next one. Stream elements (vertex or fragment arrays) are processed independently by kernels (vertex or fragment programs) and their output can be received again by another kernels.

The stream programming model allows an efficient computation, because kernels operate on independent elements from a set of input streams and can be processed using hardware like GPU, that process vertex or fragments streams in parallel. This allows making parallel computing without the complexity of traditional parallel programming models.

Computational Resources on GPU

In order to implement any kind of algorithm on GPU, there are different computational resources (Harris, 2005; Owens, 2007). By one side, current GPUs have two different parallel programmable processors: vertex and fragment processors. Vertex processors compute vertex streams (points with associated properties like position, color, normal, etc.). A vertex processor applies a vertex program to transform each input vertex to its position on the screen. Fragment processors compute fragment streams. They apply a fragment program to each fragment to calculate the final color of the pixel. In addition of using the attributes of each fragment, those processors can access to other data streams like textures when they are generating each pixel. Textures can be seen as an interface to access to read-only memory.

Another available resource in GPU is the rasterizer. It generates fragments using triangles built in from vertex and connectivity information. The rasterizer

allows generating an output set of data from a smaller input one, because it interpolates the properties of each vertex that belongs to a triangle (like color, texture coordinates, etc.) for each generated fragment.

One of the essential features of GPUs is the *render-to-texture* one. This allows storing the pixels generated by the fragments processor in a texture, instead of a screen buffer. This is at the moment the only mechanism to obtain directly output data from GPU computing. Render-to-texture cannot be thought as an interface to read-write memory, due to the fact that fragment processor can read data from a texture in multiple times, but it can write there just one time, at the end of each fragment processing.

ARTIFICIAL INTELLIGENCE ALGORITHMS ON GPU

Using the stream programming model as well as resources provided by graphics hardware, Artificial Intelligence algorithms can be parallelized and therefore computing-accelerated. The parallel and high-intensive computing nature of this kind of algorithms makes them good candidates for being implemented on the GPU.

Consider the evolution process of genetic algorithms, where a fitness value needs to be computed for each individual. Population could be considered as a data stream and fitness function as a kernel to process this stream. On GPU, for instance, the data stream must be represented as a texture, whereas the kernel must be implemented on a fragment program. Each individual's fitness would be obtained in an output stream, represented also by a texture, and obtained by the use of render-to-texture feature.

Recently some works have been realized mainly in paralleling ANN and EC algorithms, described in following sections.

Artificial Neural Networks

Bohn (1998) used GPGPU to reduce training time in Kohonen's feature maps. In this case, the bigger the map, the higher was the time reduction using the GPU. On 128x128 sized maps, time was similar using CPU and GPU, but on 512x512 sized maps, GPU was almost 3.5 times faster than CPU, increasing to 5.3 faster rates on 1024x1024 maps. This was one of the first implementations of GPGPU, made on a non-

programmable graphics system, a SiliconGraphics Infinite Reality workstation.

Later, with programmable hardware, Oh (2004) used the GPU for accelerating the process of obtaining the output of a multilayer perceptron ANN. Developed system was applied to pattern recognition obtaining 20x lower computing time than CPU implementation..

Considering another kind of ANNs, Zhongwen (2005) used GPGPU to reduce computing time in training Self-Organizing Maps (SOMs). The bigger the SOM, the higher was the reduction. Whereas using 128x128 neurons maps computing time was similar between CPU and GPU, 512x512 neuron maps involved a training process 4x faster using GPU implementation.

Bernhard (2005) used GPU to simulate Spiking Neurons model. This ANN model both requires high intensive calculations and has a parallel nature, so fits very well on GPGPU computation. Authors made different implementations depending on the neural network application. In the first case, an image segmentation algorithm was implemented using a locally-excitatory globally-inhibitory Spiking Neural Network (SNN). In this experiment, authors obtained up to 10x faster results. In the second case, SNNs were used to image segmentation using an algorithm based on histogram clustering where the ANN minimized the objective function. Here the speed was improved up to 10 times also.

Seoane (2007) showed multilayer perceptron ANN training time acceleration using GA. GPGPU techniques for ANN computing allowed accelerating it up to 11 times.

The company Evolved Machines (*Evolved Machines Website*) uses the powerful performance of GPUs to simulating of neural computation, obtaining results up to 100x faster than CPU computation.

Evolutionary Computation

In EC related works, Yu (2005) describes how parallel genetic algorithms can be mapped in low-cost graphics hardware. In their approach, chromosomes and fitness values are stored in textures. Fitness calculation and genetic operators were implemented using fragment programs on GPU. Different population sizes applied to the Colville minimization problem were used for testing, resulting in better time reductions according to bigger populations. In the case of a 128x128 sized population,

GPU genetic operators computing was 11.8 times faster than CPU, whereas in a 512x512 sized population, that rate incremented to 20.1. In fitness function computing, rates were 7.9 and 17.1 respectively.

In another work, Wong (2006) implemented Hybrid Genetic Algorithms on GPU incorporating the Cauchy mutation operator. All algorithm steps were implemented in graphics hardware, except random number generation. In this approach, a pseudo-deterministic method was proposed for selecting process, allowing significant running-time reductions. GPU implementation was 3x faster than CPU's one.

Fok (2007) showed how to implement evolutionary algorithms on GPU. Since the crossover operators of GA requires more complex calculations than mutation ones, authors studied a GPU implementation of Evolutionary Programming, using only mutation operators. Tests have been proved with the Cauchy distribution to 5 different optimization problems, obtaining between 1.25 and 5 times faster results.

FUTURE TRENDS

Nowadays GPUs are very powerful and they are evolving quite fast. By one side, there are more and more programmable elements in GPUs; by the other one, programming languages are becoming full-featured. There are more and more implementations of different kinds of general-purpose algorithms that take advantage of these features.

In Artificial Intelligence field the number of developments is rather low, in spite of the great amount of current algorithms and their high computing requirements. It seems very interesting using GPUs to extend existent implementations. For instance, some examples of speeding ANNs simulations up have been shown, however there is no works in accelerating training times. Likewise same ideas can be applied to implement other kinds of ANNs architectures or IA techniques, like in genetic programming field, where there is neither any development.

CONCLUSION

This paper has introduced general-purpose programming on GPUs. They have been shown as powerful parallel processors, which programming capabilities

allow using for general-purpose high-intensive computing algorithms. Based on this idea, existent implementations of IA models like ANN or EC on GPUs have been described, with a considerable computing time reduction.

General-purpose computing on GPU and its use to accelerating IA algorithms provides great advantages, being an essential contribution in application where computing time is a decisive factor.

KEY TERMS

Fragment: Potential pixel containing all the necessary information (color, depth, etc.) to generate the final fragment color.

Fragment Processor: Graphics system element that receives as input a set of fragments and processes it to obtain pixel, writing them in a target buffer. Present GPUs have multiple fragment processors working in parallel and can be programmed using fragment programs.

Graphics Pipeline: Three dimensional graphics oriented architecture, composed by several stages that run sequentially.

Graphics Processing Unit (GPU): Electronic device designed for graphics rendering in computers. Its architecture is specialized in graphics calculations.

General-Purpose Computation on GPUs (GPGPU): Trend in computing devices dedicated to implement general-purpose algorithms using graphics devices, called GPUs. At the moment, the high programmability and performance of GPUs allow developers run classical algorithms in these devices to speed non-graphics applications up, especially those algorithms with parallel nature.

Pixel: Picture Element abbreviation, used for referring graphic image points.

Rasterizer: Graphics Pipeline element, which from graphic primitives provides appropriate fragments to a target buffer.

Render-to-Texture: GPU feature that allows stocking the fragment processor output on a texture instead on a screen buffer.

Stream Programming Model: This parallel programming model is based on defining, by one side, sets of input and output data, called streams, and by the other side, intensive computing operations, called

kernel functions, to be applied sequentially on the streams.

Texture: In computer graphics field, it refers to a digital image used to modify the appearance of a tri-dimensional object. The operation that wraps around a texture over an object is called texture mapping. Talking about GPGPU, a texture can be considered as a data stream.

Vertex: In computer graphics field, it refers to a clearly defined point in a tridimensional space, which is processed by Graphics Pipeline. Relationships can be established between those vertices (like triangles) to assembly structures that define a tridimensional object. Talking about GPGPU, an vertex array can be considered as a data stream.

Vertex Processor: Graphics system component that receives as input a set of 3D vertex and process them to obtain 2D screen positions. Present GPUs have multiple vertex processors working in parallel and can be programmed using vertex programs.

Improving the Naïve Bayes Classifier

Liwei Fan

National University of Singapore, Singapore

Kim Leng Poh

National University of Singapore, Singapore

INTRODUCTION

A **Bayesian Network** (BN) takes a relationship between graphs and probability distributions. In the past, BN was mainly used for knowledge representation and reasoning. Recent years have seen numerous successful applications of BN in classification, among which the Naïve Bayes classifier was found to be surprisingly effective in spite of its simple mechanism (Langley, Iba & Thompson, 1992). It is built upon the strong assumption that different attributes are independent with each other. Despite of its many advantages, a major limitation of using the Naïve Bayes classifier is that the real-world data may not always satisfy the independence assumption among attributes. This strong assumption could make the prediction accuracy of the Naïve Bayes classifier highly sensitive to the correlated attributes. To overcome the limitation, many approaches have been developed to improve the performance of the Naïve Bayes classifier.

This article gives a brief introduction to the approaches which attempt to relax the independence assumption among attributes or use certain pre-processing procedures to make the attributes as independent with each other as possible. Previous theoretical and empirical results have shown that the performance of the Naïve Bayes classifier can be improved significantly by using these approaches, while the computational complexity will also increase to a certain extent.

BACKGROUND

The **Naïve Bayes classifier**, also called simple Bayesian classifier, is essentially a simple BN. Since no **structure learning** is required, it is very easy to construct and implement a Naïve Bayes classifier. Despite its simplicity, the Naïve Bayes classifier is competitive with other more advanced and sophisticated classifiers such as

decision trees (Friedman, Geiger & Goldszmidt, 1997). Owing to these advantages, the Naïve Bayes classifier has gained great popularity in solving different classification problems. Nevertheless, its **independence assumption** among attributes is often violated in the real world. Fortunately, many approaches have been developed to alleviate this problem.

In general, these approaches can be divided into two groups. One attempts to relax the independence assumption of Naïve Bayes classifier, e.g. Semi-Naïve Bayes (SNB) (Kononenko, 1991), Searching for dependencies (Pazzani, 1995), the Tree Augmented Naïve Bayes (TAN) (Friedman, Geiger & Goldszmidt, 1997), SuperParent Tree Augmented Naïve Bayes (SP-TAN) (Keogh & Pazzani, 1999), Lazy Bayes Rule (LBR) (Zheng & Webb, 2000) and Aggregating One-Dependence Estimators (AODE) (Webb, Boughton & Wang, 2005).

The other group attempts to use certain **pre-processing procedures** to select or transform the attributes, which can be more suitable for the assumption of the Naïve Bayes classifier. The Feature selection can be implemented by greedy forward search (Langley & Sage, 1994) and **Decision Trees** (Ratanamahatana & Gunopulos, 2002). The transformation techniques include **Principal Component Analysis** (PCA) (Gupta, 2004), **Independent Component Analysis** (ICA) (Prasad, 2004) and CC-ICA (Bressan & Vitria, 2002). The next section describes the main ideas of the two groups of techniques in a broad way.

IMPROVING THE NAÏVE BAYES CLASSIFIER

This section introduces the two groups of approaches that have been used to improve the **Naïve Bayes classifier**. In the first group, the strong independence assumption is relaxed by restricted structure learning. The second

group helps to select some major (and approximately independent) attributes from the original attributes or transform them into some new attributes, which can then be used by the Naïve Bayes classifier.

Relaxing the Independence Assumption

Relaxing the **independence assumption** means that the dependence will be considered in constructing the network. To consider the dependencies between attributes, Kononenko (Kononenko, 1991) proposed the Semi-Naïve Bayes classifier (SNB), which joined the attributes based on the theorem of Chebyshev. The medical diagnostic data were used to compare the performance of the SNB and the NB. It was found that the results of two domains are identical but in the other two domains SNB slightly improves the performance. Nevertheless, this method may cause overfitting problems. Another limitation of the SNB is that the number of parameters will grow exponentially with the increase of the number of attributes that need to be joined. In addition, the exhaustive searching technique of joining attributes may affect the computational time. Pazzani (Pazzani, 1995) used Forward Sequential Selection and Joining (FSSJ) and Backward Sequential Elimination and Joining (BSEJ) to search dependencies and join the attributes. They tested the two methods on UCI data and found that BSEJ provided the most improvement.

Friedman et al. (Friedman, Geiger & Goldszmidt, 1997) found that Kononenko's and Pazzani's methods can be represented as an augmented Naïve Bayes network, which includes some subgraphs. They restricted the network to be Tree Augmented Naïve Bayes (TAN) that spans over all attributes and can be learned by tree-structure learning algorithms. The results based on problems from the UCI repository showed that the TAN classifier outperforms the Naïve Bayes classifier. It is also competitive with C4.5 while maintains the computational simplicity. However, the use of the TAN classifier is only limited to the problems with discrete attributes. For the problems with continuous attributes, these attributes must be discretized. To address this problem, Friedman et al. (Friedman, Goldszmidt & Lee, 1998) extended TAN to deal with continuous attributes via parametric and semiparametric conditional probabilities. Keogh & Pazzani (Keogh & Pazzani, 1999) proposed a variant of the TAN classifier, i.e. SP-TAN, which could result

in better performance than TAN. The performance of SP-TAN is also competitive with the Lazy Bayes Rule (LBR), in which the lazy learning techniques are used in the Naïve Bayes classifier (Zheng, & Webb, 2000; Wang & Webb, 2002)

Although LBR and SP-TAN have outstanding performance on the testing data, the main disadvantage of the two methods is that they have high computational complexity. Aggregating One-Dependence Estimators (AODE), developed by Webb et al. (Webb, Boughton & Wang, 2005), can avoid model selection which may reduce computational complexity and lead to lower variance. These advantages have been demonstrated by some empirical experiment results. It is also empirically found that the average prediction accuracy of AODE is comparative to that of LBR and SP-TAN but with lower variance. Therefore, AODE might be more suitable for small datasets due to its lower variance.

Using Pre-Processing Procedures

In general, the **pre-processing procedures** for the Naïve Bayes classifier include feature selection and transforming the original attributes. The Selective Bayes classifier (SBC) (Langley & Sage, 1994) deals with correlated features by selecting only some attributes into the final classifier. They used a greedy method to search the space and forward selection to select the attributes. In their study, six UCI datasets are used to compare the performance of the Naïve Bayes classifier, SBC and C4.5. It is found that selecting the attributes can improve the performance of the Naïve Bayes classifier when there are redundant attributes. In addition, SBC is found to be competitive with C4.5 in terms of the datasets by which C4.5 outperforms the Naïve Bayes classifier. The study by Ratanamahatana & Gunopulos (Ratanamahatana & Gunopulos, 2002) applied C4.5 to select the attributes for the Naïve Bayes classifier. Interestingly, experimental results showed that the new attributes obtained by C4.5 can make the Naïve Bayes classifier outperform C4.5 with respect to a number of datasets.

Transforming the attributes is another useful pre-processing procedure for the Naïve Bayes classifier. Gupta (Gupta, 2004) found that **Principal Component Analysis** (PCA) was helpful to improve the classification accuracy and reduce the computational complexity. Prasad (Prasad, 2004) applied **Independent Component Analysis** (ICA) to all the training data and found

that the performance of Naïve Bayes classifier integrated ICA performed better than C4.5 and IB1 integrated with ICA. Bressan and Vitria (Bressan & Vitria, 2002) proposed the class-conditional ICA (CC-ICA) to do pre-processing procedure for the Naïve Bayes classifier, and found that CC-ICA based Naïve Bayes classifier outperformed the pure Naïve Bayes classifier.

Based on the UCI datasets, a detailed comparative study of PCA, ICA and CC-ICA for Naïve Bayes classifier has been carried out by Fan & Poh (Fan & Poh, 2007). PCA attempts to transform the original data into a new uncorrelated dataset, while ICA attempts to transform them into a new dataset with independent attributes. Class-conditional ICA (CC-ICA), proposed by Bressan and Vitria (2002), is built upon the idea that ICA is used to make the attributes as independent as possible for each class. In such a way, the new attributes are more reasonable than those from the PCA and ICA in order to satisfy the independence assumption of the Naïve Bayes classifier.

The datasets were limited to the continuous datasets due to the requirement of the three pre-processing procedures. The results showed that all the three pre-processing procedures can improve the performance of the Naïve Bayes classifier. It is likely due to the fact that transforming the attributes could weaken the dependence among different attributes. In addition, the discrepancy between the performance of ICA and PCA integrated with the Naïve Bayes classifier is not large. This may be an indication that PCA and ICA are competitive in improving the performance of Naïve Bayes classifier. When the number of attributes became larger, the three pre-processing procedures also improved the performance of the Naïve Bayes classifier by more.

From the methodological point of view, the CC-ICA pre-processing procedure seems to be more plausible than PCA and ICA for Naïve Bayes classifier (Bressan and Vitria, 2002; Vitria, Bressan, & Radeva, 2007). The experimental results by Fan & Poh (Fan & Poh, 2007) also showed that CC-ICA integrated with the Naïve Bayes classifier outperforms PCA and ICA integrated with the Naïve Bayes classifier in terms of classification accuracy. However, CC-ICA requires more training data to ensure that there are enough training data for each class. It is therefore suggested that the choice of a suitable pre-processing procedure should depend on the characteristics of datasets, e.g. the sample size for each class.

FUTURE TRENDS

With the development of the algorithms for learning BN, relaxing the independence assumption is promising for improving the performance of the Naïve Bayes classifier. However, relaxing the independence assumption to the unrestricted BN is not appropriate. Friedman et al. (Friedman, Geiger, & Goldszmidt, 1997) compared the Naïve Bayes classifier and Bayesian Network and found that using unrestricted BN did not improve the accuracy. On the contrary, it even reduced the accuracy in some domains. Therefore, other restricted BN may be used for improving the performance while keeping the simplicity of the Naïve Bayes classifier. Effective and simple learning algorithm is also important for the improving the performance.

On the other hand, with the development of algorithms for machine learning, more pre-processing procedures are expected to be developed for selecting or transforming the attributes. One possible way to get better performance is to combine feature selection with transformation techniques to do the pre-processing procedures. Among the alternative techniques for doing pre-processing procedures, the most promising one might be ICA. The reason is that the motivation of the pre-processing procedures is to derive the attributes satisfying the independence assumption for the Naïve Bayes classifier while the objective of ICA is to find the independent components. However, there are also some limitations on the use of ICA, e.g. the requirements of continuous datasets and a large number of training samples. How to overcome these limitations is therefore a potential area for future research.

CONCLUSION

This article briefly discusses the techniques which can be used to improve the performance of the Naïve Bayes classifier. The general idea is to overcome the limitation of the strong independence assumption of the **Naïve Bayes classifier**. Relaxing the strong assumption is a natural way and has been studied from different viewpoints. All the approaches relaxing the assumption discussed in the article is restricted **Bayesian Networks**, which are still most practicable techniques. In addition, pre-processing procedures are also very useful to make the attributes to satisfy the independence assumption. However, using these approaches increases the compu-

tational complexity to a certain extent. It would be useful to model correlations among appropriate attributes that can be captured by simple restricted structure but with good performance.

KEY TERMS

Decision Trees: Decision tree is a classifier in the form of a tree structure, where each node is either a leaf node or a decision node. A decision tree can be used to classify an instance by starting at the root of the tree and moving through it until a leaf node, which provides the classification of the instance. A well known and frequently used algorithm of decision tree over the years is C4.5.

Forward Selection and Backward Elimination: A forward selection method would start with the empty set and successively add attributes, while a backward

elimination process would begin with the full set and remove unwanted ones.

Greedy Search: At each point in the search, the algorithm considers all local changes to the current set of attributes, makes its best selection, and never reconsiders this choice.

Independent Component Analysis (ICA): Independent component analysis (ICA) is a newly developed technique for finding hidden factors or components to give a new representation of multivariate data. ICA could be thought of as a generalization of PCA. PCA tries to find uncorrelated variables to represent the original multivariate data, whereas ICA attempts to obtain statistically independent variables to represent the original multivariate data.

Naïve Bayes Classifier: The Naïve Bayes classifier, also called simple Bayesian classifier, is essentially a

simple Bayesian Network (BN). There exist two underlying assumptions in the Naïve Bayes classifier. First, all attributes are independent with each other given the classification variable. Second, all attributes are directly dependent on the classification variable. Naïve Bayes classifier computes the posterior of classification variable given a set of attributes by using the Bayes rule under the conditional independence assumption.

Principal Component Analysis (PCA): PCA is a popular tool for multivariate data analysis, feature extraction and data compression. Given a set of multivariate measurements, the purpose of PCA is to find a set of variables with less redundancy. The redundancy is measured by correlations between data elements.

UCI Repository: This is a repository of databases, domain theories and data generator that are used by the machine learning community for the empirical analysis of machine learning algorithms.

Incorporating Fuzzy Logic in Data Mining Tasks

Lior Rokach

Ben Gurion University, Israel

In this chapter we discuss how fuzzy logic extends the envelop of the main data mining tasks: clustering, classification, regression and association rules. We begin by presenting a formulation of the data mining using fuzzy logic attributes. Then, for each task, we provide a survey of the main algorithms and a detailed description (i.e. pseudo-code) of the most popular algorithms.

INTRODUCTION

There are two main types of uncertainty in supervised learning: statistical and cognitive. Statistical uncertainty deals with the random behavior of nature and all existing data mining techniques can handle the uncertainty that arises (or is assumed to arise) in the natural world from statistical variations or randomness. Cognitive uncertainty, on the other hand, deals with human cognition.

Fuzzy set theory, first introduced by Zadeh in 1965, deals with cognitive uncertainty and seeks to overcome many of the problems found in classical set theory. For example, a major problem faced by researchers of control theory is that a small change in input results in a major change in output. This throws the whole control system into an unstable state. In addition there was also the problem that the representation of subjective knowledge was artificial and inaccurate. Fuzzy set theory is an attempt to confront these difficulties and in this chapter we show how it can be used in data mining tasks.

BACKGROUND

Data mining is a term coined to describe the process of sifting through large and complex databases for identifying valid, novel, useful, and understandable patterns and relationships. Data mining involves the inferring of algorithms that explore the data, develop

the model and discover previously unknown patterns. The model is used for understanding phenomena from the data, analysis and prediction. The accessibility and abundance of data today makes knowledge discovery and data mining a matter of considerable importance and necessity.

We begin by presenting some of the basic concepts of fuzzy logic. The main focus, however, is on those concepts used in the induction process when dealing with data mining. Since fuzzy set theory and fuzzy logic are much broader than the narrow perspective presented here, the interested reader is encouraged to read Zimmermann (2005).

In classical set theory, a certain element either belongs or does not belong to a set. Fuzzy set theory, on the other hand, permits the gradual assessment of the membership of elements in relation to a set.

Let U be a universe of discourse, representing a collection of objects denoted generically by u . A fuzzy set A in a universe of discourse U is characterized by a membership function μ_A which takes values in the interval $[0, 1]$. Where $\mu_A(u) = 0$ means that u is definitely not a member of A and $\mu_A(u) = 1$ means that u is definitely a member of A .

The above definition can be illustrated on the vague set of *Young*. In this case the set U is the set of people. To each person in U , we define the degree of membership to the fuzzy set *Young*. The membership function answers the question "to what degree is person u young?". The easiest way to do this is with a membership function based on the person's age. For example Figure 1 presents the following membership function:

$$\mu_{Young}(u) = \begin{cases} 0 & \text{age}(u) > 32 \\ 1 & \text{age}(u) < 16 \\ \frac{32 - \text{age}(u)}{16} & \text{otherwise} \end{cases} \quad (1)$$

Figure 1. Membership function for the young set

Given this definition, John, who is 18 years old, has degree of youth of 0.875. Philip, 20 years old, has degree of youth of 0.75. Unlike probability theory, degrees of membership do not have to add up to 1 across all objects and therefore either many or few objects in the set may have high membership. However, an object's

membership in a set (such as “young”) and the set's complement (“not young”) must still sum to 1.

The main difference between classical set theory and fuzzy set theory is that the latter admits to partial set membership. A classical or crisp set, then, is a fuzzy set that restricts its membership values to $\{0,1\}$, the

Figure 2. Membership function for the crisp young set

endpoints of the unit interval. Membership functions can be used to represent a crisp set. For example, Figure 2 presents a crisp membership function defined as:

$$\mu_{CrispYoung}(u) = \begin{cases} 0 & age(u) > 22 \\ 1 & age(u) \leq 22 \end{cases} \quad (2)$$

In regular classification problems, we assume that each instance takes one value for each attribute and that each instance is classified into only one of the mutually exclusive classes. To illustrate how fuzzy logic can help data mining tasks, we introduce the problem of modeling the preferences of TV viewers. In this problem there are 3 input attributes: $A = \{\text{Time of Day, Age Group, Mood}\}$. The classification can be the movie genre that the viewer would like to watch, such as $C = \{\text{Action, Comedy, Drama}\}$. All the attributes are vague by definition. For example, people's feelings of happiness, indifference, sadness, sourness and grumpiness are vague without any crisp boundaries between them. Although the vagueness of "Age Group" or "Time of Day" can be avoided by indicating the exact age or exact time, a rule induced with a crisp decision tree may then have an artificial crisp boundary, such as "IF Age < 16 THEN action movie". But how about someone who is 17 years of age? Should this viewer definitely not watch an action movie? The viewer preferred genre may still be vague. For example, the viewer may be in a mood for both comedy and drama movies. Moreover, the association of movies into genres may also be vague. For instance the movie "Lethal Weapon" (starring Mel Gibson and Danny Glover) is considered to be both comedy and action movie.

Fuzzy concept can be introduced into a classical data mining task if at least one of the attributes is fuzzy. In the example described above, both input and target attributes are fuzzy. Formally the problem is defined as following: Each class c_j is defined as a fuzzy set on the universe of objects U . The membership function $\mu_{c_j}(u)$ indicates the degree to which object u belongs to class c_j . Each attribute a_i is defined as a linguistic attribute which takes linguistic values from $dom(a_i) = \{v_{i,1}, v_{i,2}, \dots, v_{i,|dom(a_i)|}\}$. Each linguistic value $v_{i,k}$ is also a fuzzy set defined on U . The membership $\mu_{v_{i,k}}(u)$ specifies the degree to which object u 's attribute a_i is $v_{i,k}$. Recall that the membership of a linguistic value can be subjectively assigned or transferred from numerical values by a membership function defined on the range of the numerical value.

Typically, before one can incorporate fuzzy concepts into a data mining application, an expert is required to provide the fuzzy sets for the quantitative attributes, along with their corresponding membership functions (Mitra and Pal, 2005). Alternatively the appropriate fuzzy sets are determined using fuzzy clustering.

MAIN FOCUS OF THE CHAPTER

Fuzzy Supervised Learning

In this section we survey supervised methods that incorporate fuzzy sets. Supervised methods are methods that attempt to discover the relationship between input attributes and a target attribute (sometimes referred to as a dependent variable). The relationship discovered is represented in a structure referred to as a model. Usually models describe and explain phenomena, which are hidden in the dataset and can be used for predicting the value of the target attribute knowing the values of the input attributes.

It is useful to distinguish between two main supervised models: classification models (classifiers) and Regression Models. Regression models map the input space into a real-value domain. For instance, a regressor can predict the demand for a certain product given its characteristics. On the other hand, classifiers map the input space into pre-defined classes.

Fuzzy set theoretic concepts can be incorporated at the input, output, or into to backbone of the classifier. The data can be presented in fuzzy terms and the output decision may be provided as fuzzy membership values (Peng, 2004). In this chapter we will concentrate on fuzzy decision trees. The interested reader is encouraged to read also about soft regression (Shnaider et al., 1997) and Neuro-fuzzy (Mitra and Hayashi, 2000, Nauck, 1997).

Decision tree is a predictive model which can be used to represent classifiers. Decision trees are frequently used in applied fields such as finance, marketing, engineering and medicine. Decision tree are self-explained. There is no need to be an expert in data mining in order to follow a certain decision tree.

There are several algorithms for induction of fuzzy decision trees (Olaru and Wehenkel, 2003), most of them extend existing decision trees methods such as: Fuzzy-CART (Jang, 1994), Fuzzy-ID3 (Cios and Sztandera, 1992; Maher and Clair, 1993). Another complete

framework for building a fuzzy tree including several inference procedures based on conflict resolution in rule-based systems and efficient approximate reasoning methods was presented in (Janikow, 1998).

In this section we will focus on the algorithm proposed in Yuan and Shaw (1995). This algorithm can handle the classification problems with both fuzzy attributes and fuzzy classes represented in linguistic fuzzy terms. It can also handle other situations in a uniform way where numerical values can be fuzzified to fuzzy terms and crisp categories can be treated as a special case of fuzzy terms with zero fuzziness. The algorithm uses classification ambiguity as fuzzy entropy. The classification ambiguity directly measures the quality of classification rules at the decision node. It can be calculated under fuzzy partitioning and multiple fuzzy classes.

When a certain attribute is numerical, it needs to be fuzzified into linguistic terms before it can be used in the algorithm (Hong et al., 1999). The fuzzification process can be performed manually by experts or can be derived automatically using some sort of clustering algorithm. Clustering groups the data instances into subsets in such a manner that similar instances are grouped together; different instances belong to different groups. The instances are thereby organized into an efficient representation that characterizes the population being sampled.

One can use a simple algorithm to generate a set of membership functions on numerical data. Assume attribute a_i has numerical value x from the domain X . We can cluster X to k linguistic terms $v_{i,j}$, $j = 1, \dots, k$. The size of k is manually predefined. Figure 3 illustrates the creation of four groups defined on the age attribute: "young", "early adulthood", "middle-aged" and "old age". Note that the first set ("young") and the last set ("old age") have a trapezoidal form which can be uniquely described by the four corners. For example, the "young" set could be represented as (0,0,16,32). In between, all other sets ("early adulthood" and "middle-aged") have a triangular form which can be uniquely described by the three corners. For example, the set "early adulthood" is represented as (16,32,48).

The induction algorithm of fuzzy decision tree measures the classification ambiguity associated with each attribute and split the data using the attribute with the smallest classification ambiguity. The classification ambiguity of attribute a_i with linguistic terms $v_{i,j}$, $j = 1, \dots, k$ on fuzzy evidence S , denoted as $G(a_i | S)$, is the weighted average of classification ambiguity calculated as:

$$G(a_i | S) = \sum_{j=1}^k w(v_{i,j} | S) \cdot G(v_{i,j} | S) \quad (3)$$

Figure 3. Membership function for various groups in the age attribute

where $w(v_{ij} | S)$ is the weight which represents the relative size of v_{ij} and is defined as:

$$w(v_{ij} | S) = \frac{M(v_{ij} | S)}{\sum_k M(v_{ik} | S)} \quad (4)$$

The classification ambiguity of v_{ij} is defined as

$$G(v_{ij} | S) = g\left(\bar{p}\left(C | v_{ij}\right)\right),$$

which is measured based on the possibility distribution vector

$$\bar{p}\left(C | v_{ij}\right) = \left(p\left(c_1 | v_{ij}\right), \dots, p\left(c_k | v_{ij}\right)\right).$$

Given v_{ij} , the possibility of classifying an object to class c_l can be defined as:

$$p\left(c_l | v_{ij}\right) = \frac{S(v_{ij}, c_l)}{\max_k S(v_{ij}, c_k)} \quad (5)$$

where $S(A, B)$ is the fuzzy subethood that measures the degree to which A is a subset of B . The subethood can be used to measure the truth level of the rule of classification rules. For example given a classification rule such as "IF Age is Young AND Mood is Happy THEN Comedy" we have to calculate $S(Hot \cap Sunny, Swimming)$ in order to measure the truth level of the classification rule.

The function $g(\bar{p})$ is the possibilistic measure of ambiguity or nonspecificity and is defined as:

$$g(\bar{p}) = \sum_{i=1}^{|\bar{p}|} \left(p_i^* - p_{i+1}^*\right) \cdot \ln(i) \quad (6)$$

where

$$\bar{p}^* = (p_1^*, \dots, p_{|\bar{p}|}^*)$$

is the permutation of the possibility distribution \bar{p} sorted such that $p_i^* \geq p_{i+1}^*$. All the above calculations are carried out at a predefined significant level α . An instance will take into consideration of a certain branch v_{ij} only if its corresponding membership is greater

than α . This parameter is used to filter out insignificant branches.

After partitioning the data using the attribute with the smallest classification ambiguity, the algorithm looks for nonempty branches. For each nonempty branch, the algorithm calculates the truth level of classifying all instances within the branch into each class. The truth level is calculated using the fuzzy subethood measure $S(A, B)$.

If the truth level of one of the classes is above a predefined threshold β then no additional partitioning is needed and the node become a leaf in which all instance will be labeled to the class with the highest truth level. Otherwise the procedure continues in a recursive manner. Note that small values of β will lead to smaller trees with the risk of underfitting. A higher β may lead to a larger tree with higher classification accuracy. However, at a certain point, higher values β may lead to overfitting.

In a regular decision tree, only one path (rule) can be applied for every instance. In a fuzzy decision tree, several paths (rules) can be applied for one instance. In order to classify an unlabeled instance, the following steps should be performed:

- Step 1: Calculate the membership of the instance for the condition part of each path (rule). This membership will be associated with the label (class) of the path.
- Step 2: For each class calculate the maximum membership obtained from all applied rules.
- Step 3: An instance may be classified into several classes with different degrees based on the membership calculated in Step 2.

Fuzzy Clustering

The goal of clustering is descriptive, that of classification is predictive. Since the goal of clustering is to discover a new set of categories, the new groups are of interest in themselves, and their assessment is intrinsic. In classification tasks, however, an important part of the assessment is extrinsic, since the groups must reflect some reference set of classes.

Clustering groups data instances into subsets in such a manner that similar instances are grouped together, while different instances belong to different groups. The instances are thereby organized into an efficient representation that characterizes the population being

sampled. Formally, the clustering structure is represented as a set of subsets $C = C_1, \dots, C_k$ of S , such that:

$$S = \bigcup_{i=1}^k C_i$$

and $C_i \cap C_j = \emptyset$ for $i \neq j$. Consequently, any instance in S belongs to exactly one and only one subset.

Traditional clustering approaches generate partitions; in a partition, each instance belongs to one and only one cluster. Hence, the clusters in a hard clustering are disjointed. Fuzzy clustering (Nasraoui and Krishnapuram, 1997, Shnaider et al., 1997) extends this notion and suggests a *soft clustering* schema. In this case, each pattern is associated with every cluster using some sort of membership function, namely, each cluster is a fuzzy set of all the patterns. Larger membership values indicate higher confidence in the assignment of the pattern to the cluster. A hard clustering can be obtained from a fuzzy partition by using a threshold of the membership value.

The most popular fuzzy clustering algorithm is the fuzzy c -means (FCM) algorithm. FCM is an iterative algorithm. The aim of FCM is to find cluster centers (centroids) that minimize a dissimilarity function. To accommodate the introduction of fuzzy partitioning, the membership matrix (U) is randomly initialized according to Equation 7.

$$\sum_{i=1}^c u_{ij} = 1, \forall j = 1, \dots, n \quad (7)$$

The algorithm minimizes a dissimilarity (or distance) function which is given in Equation 13:

$$J(U, c_1, c_2, \dots, c_c) = \sum_{i=1}^c J_i = \sum_{i=1}^c \sum_{j=1}^n u_{ij}^m d_{ij}^2 \quad (8)$$

where, u_{ij} is between 0 and 1; c_i is the centroid of cluster i ; d_{ij} is the Euclidian distance between i -th centroid and j -th data point; m is a weighting exponent.

To reach a minimum of dissimilarity function there are two conditions. These are given in Equation 9 and Equation 10.

$$c_i = \frac{\sum_{j=1}^n u_{ij}^m x_j}{\sum_{j=1}^n u_{ij}^m} \quad (9)$$

$$u_{ij} = \frac{1}{\sum_{k=1}^c \left(\frac{d_{ij}}{d_{kj}} \right)^{2/(m-1)}} \quad (10)$$

By iteratively updating the cluster centers and the membership grades for each data point, FCM iteratively moves the cluster centers to the “right” location within a data set. However, FCM does not ensure that it converges to an optimal solution. The random initialization of U might have uncanceled effect on the final performance.

Fuzzy Association Rules

Association rules are rules of the kind “70% of the customers who buy vine and cheese also buy grapes”. While the traditional field of application is market basket analysis, association rule mining has been applied to various fields since then, which has led to a number of important modifications and extensions.

A fuzzy association algorithm is proposed in Komem and Schneider (2005). The quantitative values are first transformed into a set of membership grades, by using predefined membership functions. Every membership grade represents the agreement of a quantitative value with a linguistic term. In order to avoid discriminating the importance level of data, each point must have membership grade of 1 in one membership function; Thus, the membership functions of each attribute produce a continuous line of $\mu = 1$. Additionally, in order to diagnose the bias direction of an item from the center of a membership function region, almost each point get another membership grade which is lower than 1 in other membership functions region. Thus, each end of membership function region is touching, close to, or slightly overlapping an end of another membership function (except the outside regions, of course).

By this mechanism, as point “a” moves right, further from the center of the region “middle”, it gets a higher value of the label “middle-high”, additionally to the value 1 of the label “middle”.

FUTURE TRENDS

Some of the challenges of using fuzzy theory in data mining tasks, include the following:

1. Incorporation of domain knowledge for improving the fuzzy modeling.
2. Developing methods for presenting fuzzy data model to the end-users.
3. Efficient integration of fuzzy logic in data mining tools.
4. A hybridization of fuzzy sets with data mining techniques.

CONCLUSIONS

This chapter discussed how fuzzy logic can be used to solve several different data mining tasks, namely classification clustering, and discovery of association rules. The discussion focused mainly one representative algorithm for each of these tasks.

There are at least two motivations for using fuzzy logic in data mining, broadly speaking. First, as mentioned earlier, fuzzy logic can produce more abstract and flexible patterns, since many quantitative features are involved in data mining tasks. Second, the crisp usage of metrics is better replaced by fuzzy sets that can reflect, in a more natural manner, the degree of belongingness/membership to a class or a cluster.

KEY TERMS

Association Rules: Techniques that find in a database conjunctive implication rules of the form “X and Y implies A and B.”

Attribute: A quantity describing an instance. An attribute has a domain defined by the attribute type, which denotes the values that can be taken by an attribute.

Classifier: A structured model that maps unlabeled instances to finite set of classes.

Clustering: The process of grouping data instances into subsets in such a manner that similar instances are grouped together into the same cluster, while different instances belong to different clusters.

Data Mining: The core of the KDD process, involving the inferring of algorithms that explore the data, develop the model, and discover previously unknown patterns.

Fuzzy Logic: A type of logic that recognizes more than simple true and false values. With fuzzy logic, propositions can be represented with degrees of truth-

fulness and falsehood thus it can deal with imprecise or ambiguous data. Boolean logic is considered to be a special case of fuzzy logic.

Instance: A single object of the world from which a model will be learned, or on which a model will be used.

Knowledge Discovery in Databases (KDD): A nontrivial exploratory process of identifying valid, novel, useful, and understandable patterns from large and complex data repositories.

Independent Subspaces

INTRODUCTION

Several unsupervised learning topics have been extensively studied with wide applications for decades in the literatures of statistics, signal processing, and machine learning. The topics are mutually related and certain connections have been discussed partly, but still in need of a systematical overview. The article provides a unified perspective via a general framework of independent subspaces, with different topics featured by differences in choosing and combining three ingredients. Moreover, an overview is made via three streams of studies. One consists of those on the widely studied principal component analysis (PCA) and factor analysis (FA), featured by the second order independence. The second consists of studies on a higher order independence featured independent component analysis (ICA), binary FA, and nonGaussian FA. The third is called mixture based learning that combines individual jobs to fulfill a complicated task. Extensive literatures make it impossible to provide a complete review. Instead, we aim at sketching a roadmap for each stream with attentions on those topics missing in the existing surveys and textbooks, and limited to the authors' knowledge.

A GENERAL FRAMEWORK OF INDEPENDENT SUBSPACES

A number of unsupervised learning topics are featured by its handling on a fundamental task. As shown in Fig.1(b), every sample \mathbf{x} is projected into $\hat{\mathbf{x}}$ on a manifold and the error $\mathbf{e} = \mathbf{x} - \hat{\mathbf{x}}$ of using $\hat{\mathbf{x}}$ to represent \mathbf{x} is minimized collectively on a set of samples. One widely studied situation is that a manifold is a subspace represented by linear coordinates, e.g., spanned by three linear independent basis vectors $\mathbf{a}_1, \mathbf{a}_2, \mathbf{a}_3$ as shown in Fig.1(a). So, $\hat{\mathbf{x}}$ can be represented by its projection $y^{(j)}$ on each basis vector, i.e.,

$$\hat{\mathbf{x}} = \sum_j^3 y^{(j)} \mathbf{a}_j$$

or

$$\mathbf{x} = \hat{\mathbf{x}} + \mathbf{e} = \mathbf{A}\mathbf{y} + \mathbf{e}, \quad [\mathbf{y} = y^{(1)}, y^{(2)}, y^{(3)}]^T. \quad (1)$$

Typically, the error $\mathbf{e} = \mathbf{x} - \hat{\mathbf{x}}$ is measured by the square norm, which is minimized when \mathbf{e} is orthogonal to $\hat{\mathbf{x}}$. Collectively, the minimization of the average error $\|\mathbf{e}\|^2$ on a set of samples or its expectation $E\|\mathbf{e}\|^2$ is featured by those natures given at the bottom of Fig.1(a).

Generally, the task consists of three ingredients, as shown in Fig.2. First, how the error $\mathbf{e} = \mathbf{x} - \hat{\mathbf{x}}$ is measured. Different measures define different projections. The square norm $\mathbf{d} = \|\mathbf{e}\|^2$ applies to a homogeneous medium between \mathbf{x} and $\hat{\mathbf{x}}$. Other measures are needed for inhomogeneous mediums. In Fig.1(c), a non-orthogonal but still linear projection is considered via $\mathbf{d} = \|\mathbf{e}\|_B^2 = \mathbf{e}^T \Sigma_e^{-1} \mathbf{e}$ with $\Sigma_e^{-1} = \mathbf{B}^T \mathbf{B}$, as if \mathbf{e} is first mapped to a homogeneous medium by a linear mapping \mathbf{e} and then measured by the square norm. Shown at the bottom of Fig.1(c) are the natures of this $\text{Min}\|\mathbf{e}\|_B^2$. Being considerably different from those of $\text{Min}\|\mathbf{e}\|^2$, more assumptions have to be imposed externally.

The second ingredient is a coordinate system, via either linear vectors in Fig.1(a)&(c) or a set of curves on a nonlinear manifold in Fig.1(b). Moreover, there is the third ingredient that imposes certain structure to further constrict how \mathbf{y} is distributed within the coordinates, e.g., by the nature \mathbf{d} .

The differences in choosing and combining the three ingredients lead to different approaches. We use the name "independent subspaces" to denote those structures with the components of \mathbf{y} being mutually independent, and get a general framework for accommodating several unsupervised learning topics.

Subsequently, we summarize them via three streams of studies by considering

- $\mathbf{d} = \|\mathbf{e}\|_B^2 = \mathbf{e}^T \Sigma_e^{-1} \mathbf{e}$ and two special cases,
- three types of independence structure, and whether there is temporal structure among samples,
- varying from one linear coordinate system to multiple linear coordinate systems at different locations, as shown in Fig.2.

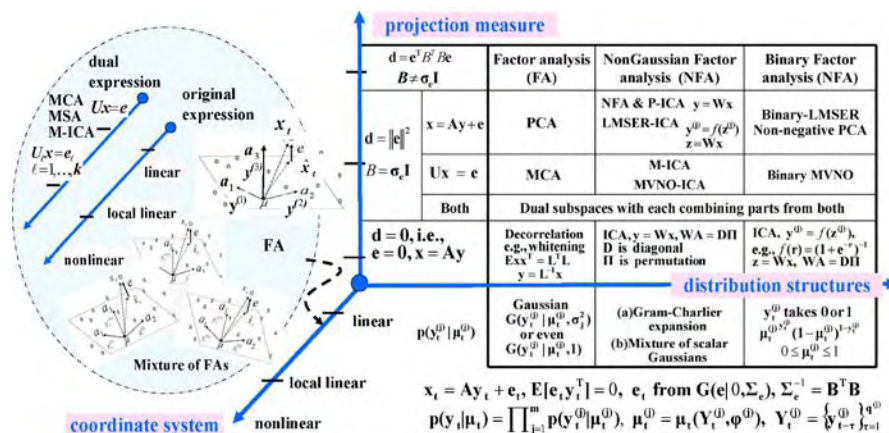

Fig.2 Three gradients and their typical choices

STUDIES FEATURED BY SECOND ORDER INDEPENDENCE

We start at considering samples of independently and identically distributed (i.i.d.) by linear coordinates and an independent structure of a Gaussian $\mathbf{p}(\mathbf{y}_i^{(j)} | \mathbf{1}^{(j)})$, with the projection measure varying as illustrated within the first column of the table in Fig.2. We encounter factor analysis (FA) in the general case $d = \|\mathbf{e}\|_B^2 = \mathbf{e}^T \mathbf{B}^T \mathbf{B} \mathbf{e}$. At the special case $\mathbf{B} = \sigma_e \mathbf{I}$, the linear coordinates span a principal subspace of data. Further imposing $\mathbf{A}^T \mathbf{A} = \mathbf{I}$ and requiring the columns of \mathbf{A} given by the first m principal components (PCs), i.e., eigenvectors that correspond the largest eigenvalues of $\Sigma = (\mathbf{B}^T \mathbf{B})^{-1}$. It becomes equivalent to PCA. Moreover, at the de-generated case $e = 0$, $y = xW$ de-correlates components of y , e.g., performing a pre-whitening as encountered in signal processing.

We summarize studies on the Roadmap A. The first stream originated from 100 years ago. The first adaptive learning one is Oja rule that finds the 1st-PC (i.e., the eigenvector that corresponds the largest eigenvalue of Σ), without explicitly estimating Σ . Extended to find multi-PCs, one way is featured by either an asymmetrical or a sequential implementation of the 1st-PC rule, but suffering error-accumulation. Details are referred to Refs.5,6,7,76,96 in (Xu, 2007a). The other way is finding multi-PCs symmetrically, e.g., Oja subspace rule. Further studies are summarized into the following branches:

MCA, Dual Subspace, and TLS Fitting

In (Xu, Krzyzak&Oja, 1991), a dual pattern recognition is suggested by considering both the principal subspace and its complementary subspace, as well as both the multiple PCs and its complementary counterparts--the components that correspond the smallest eigenvalues of Σ (i.e., the row vectors of \mathbf{U} in Fig.2). Moreover, the first adaptive rule is proposed by eqn.(11a) in (Xu, Krzyzak&Oja, 1991) to get the component that corresponds the smallest eigenvalue of Σ , under the name Minor component analysis (MCA) firstly coined by Xu, Oja&Suen (1992), and it is also used for implementing a total least square (TLS) curve fitting. Subsequently, this topic has been brought to the signal processing literature by Gao, Ahmad & Swamy (1992) that was motivated by a visit of Gao to Xu's office where Xu introduced him the result of Xu, Oja&Suen (1992). Thereafter, adap-

tive MCA learning for TLS filtering becomes a popular topic of signal processing, see (Feng,Bao&Jiao,1998) and Refs.24,30,58,60 in (Xu,2007a).

It was also suggested in (Xu,Krzyzak&Oja,1992) that an implementation of PCA or MCA is made by switching the updating sign in the above eqn.(11a). Efforts were subsequently made to examine the existing PCA rules on whether they remain stable after such a sign switching. These jobs usually need tedious mathematical analyses of ODE stability, e.g., Chen & Amari (2001). An alternative way is turning an optimization of a PCA cost into a stable optimization of an induced cost for MCA, e.g., the LMSE cost is turned into one for subspace spanned by multiple MCs (Xu, 1994, see Ref.111, Xu2007a). A general method is further given by eqns(24-26) in (Xu, 2003) and then discussed in (Xu, 2007a).

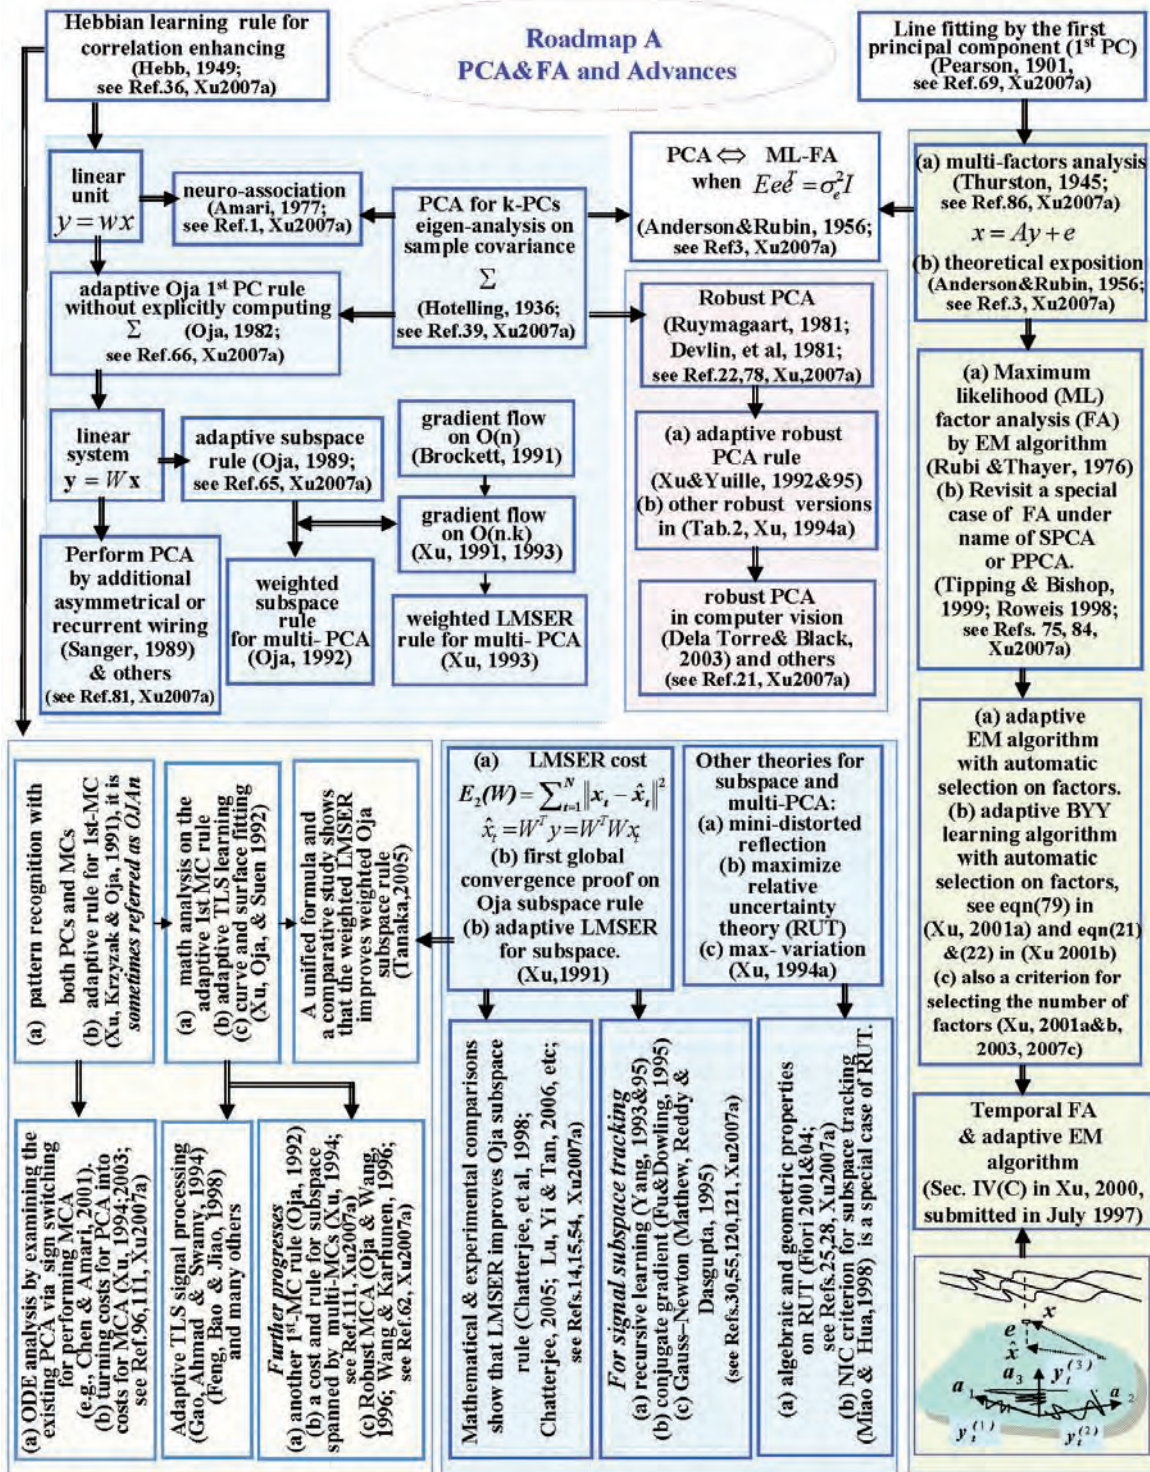

LMSE Learning and Subspace Tracking

A new adaptive PCA rule is derived from the gradient $\nabla E_2(W)$ for a least mean square error reconstruction (LMSE) (Xu,1991), with the first proof proposed on global convergence of Oja subspace rule--a task that was previously regarded as difficult. It was shown mathematically and experimentally that LMSE improves Oja rule by further comparative studies, e.g, see (Karhunen,Pajunen&Oja,1998) and see (Refs14,15,48,54,71,72, Xu2007a). Two years after (Xu,1991), this $E_2(W)$ is used for signal subspace tracking via a recursive least square technique (Yang,1993), then followed by others in the signal processing literature (Refs.33&55, Xu2007a). Also, PCA and subspace analysis can be performed by other theories or costs (Xu, 1994a&b). The algebraic and geometric properties were further analyzed on one of them, namely relative uncertainty theory (RUT), by Fiori (2000&04, see Refs.25,29, Xu2007a). Moreover, the NIC criterion for subspace tracking is actually a special case of this RUT, which can be observed by comparing eqn.(20) in (Miao& Hua,1998) with the equation of \mathcal{P}_e at the end of Sec.III.B in (Xu,1994a).

Principal Subspace vs. Multi-PCs

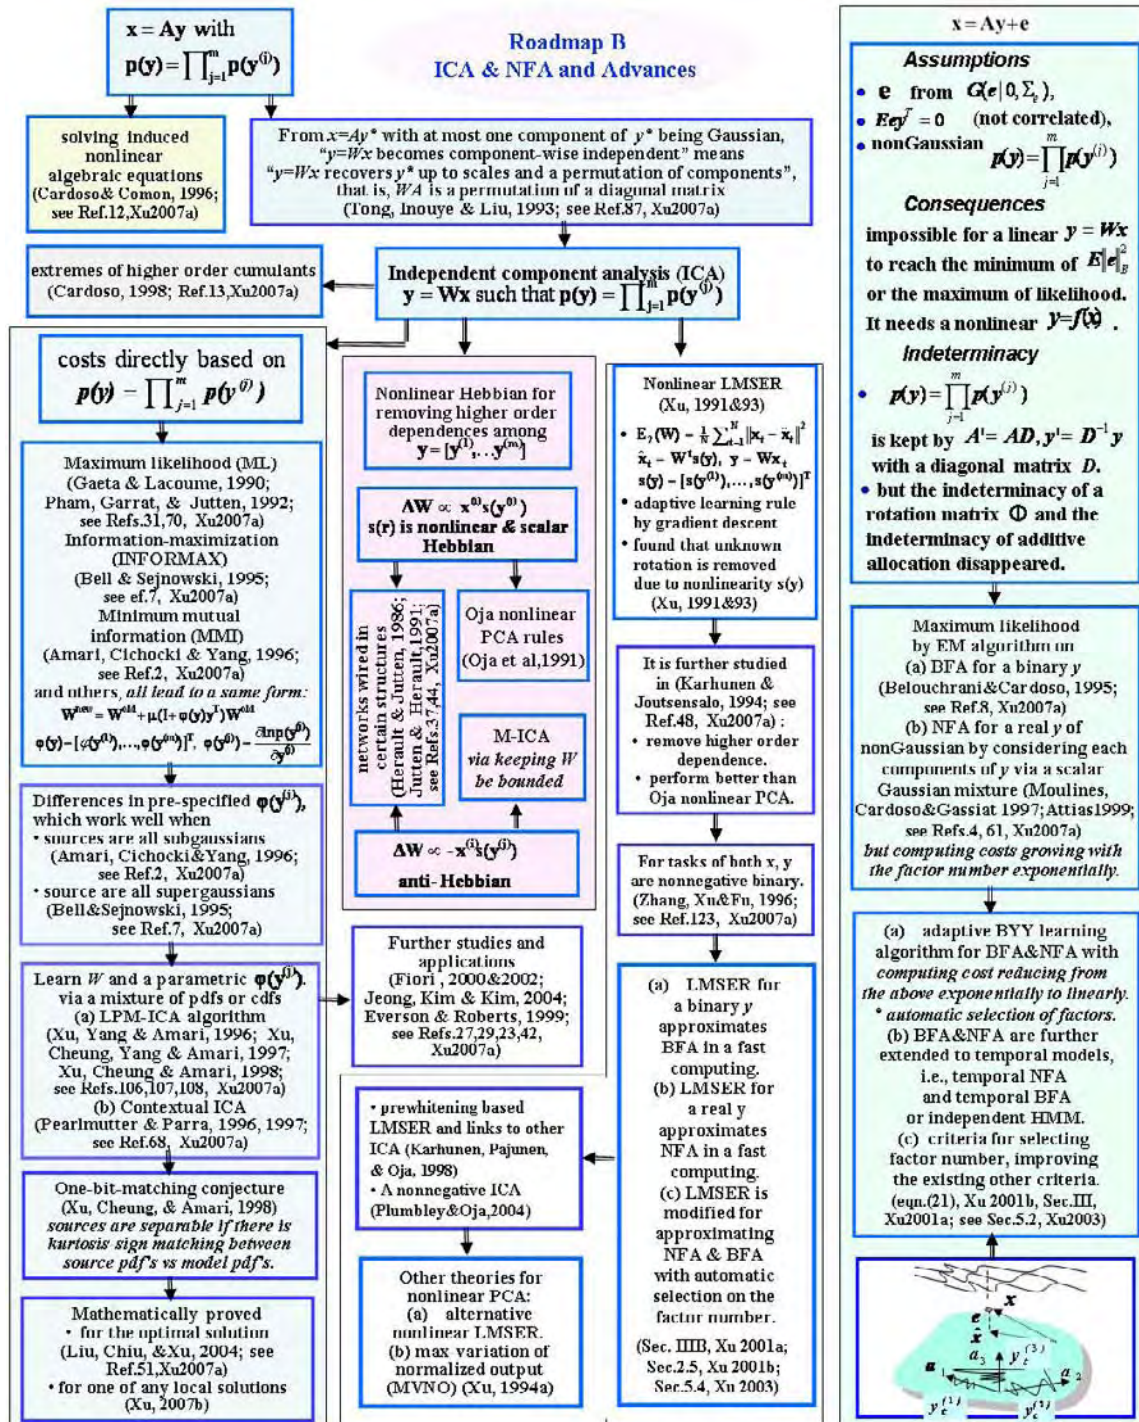

Oja subspace rule does not truly find the multi-PCs due to a rotation indeterminacy. Interestingly, it is demonstrated experimentally that adding a sigmoid function makes LMSE approximate the multi-PCs

Figure 3.

Note: due to a limited space, it is impossible to put all the references into the reference list of this article. The problem is solved in help of (Xu, 2007a) via citing papers in its reference list where there are 123 entries. E.g., “see Refs.22,78, Xu2007a” means “see the entries [22][78] in the reference list of (Xu, 2007a).

Figure 4.

well (Xu,1991). Working at Harvard in the late summer 1991, Xu got aware of Brockett (1991) and thus extended the Brockett flow of $n \times n$ orthogonal matrices to that of $n \times n_1$ orthogonal matrices with $n > n_1$, from which two learning rules for truly the multi-PCs are obtained through modifying the LMSER rule and Oja subspace rule. The two rules were included as eqns (13)&(14) in Xu (1993) that was submitted in 1991, which are independent and also different from Oja (1992). Recently, Tanaka (2005) unifies these rules into one expression controlled by one parameter, and a comparative study was made to show that eqn(14) in (Xu,1993) turned out to be the most promising one.

Adaptive Robust PCA

In the statistics literature, robust PCA was proposed to resist outliers via a robust estimator on Σ . Xu&Yuille (1992&95) generalized the rules of Oja, LMSER, and MCA into robust adaptive learning by statistical physics, related to the Huber M-estimators. Also, the PCA costs in (Xu,1994b) are extended to robust versions in Tab.2 of (Xu, 1994a). Thereafter, efforts have been further made, including its use in computer vision, e.g., see (Refs9,21,45,52, Xu2007a).

On Roadmap A, another branch consists of advances on FA, which includes PCA as its special case at $\Sigma_e = \sigma_e^2 I$. In the past decade, there is a renewed interest on FA, not only the EM algorithm for FA is brought to implementing PCA, but also adaptive EM algorithm and other advances are developed in help of the Bayesian Ying Yang (BYY) harmony learning.

SUBSPACES OF HIGHER ORDER INDEPENDENCE

Noticing the table in Fig.2, we proceed as $\mathbf{p}(\mathbf{y}_t^{(j)} | \boldsymbol{\mu}^{(j)})$ becomes nonGaussian ones in the last two columns. Shown at the left-upper corner on Roadmap B, the degenerated case $e = 0$ leads to the problem of solving $x = Ay$ from samples of x and an independence constraint

$$p(\mathbf{y}) = \prod_{j=1}^m p(\mathbf{y}^{(j)})$$

One way is solving induced nonlinear algebraic equations. Another way is called independent com-

ponent analysis (ICA), tackled in the following four branches:

- Seeking extremes of the higher order cumulants of y .
- Using nonlinear Hebbian learning for removing higher order dependences among components of y , actually from which ICA studies originate.
- Optimizing a cost that bases on

$$p(\mathbf{y}) = \prod_{j=1}^m p(\mathbf{y}^{(j)})$$

directly. As shown on Roadmap B, a same updating equation is reached from several aspects, with actual differences coming from pre-specifying the nonlinearity of $f(y^{(j)})$. One works when the source components of y^* are all subgaussians while the other works when the components of y^* are all supergaussians. This problem is solved by learning jointly W and $f(y^{(j)})$ via a parametric model. It is further found that a rough estimate of each source is already enough, which motivates the so called one-bit-matching conjecture that is recently proved to be true mathematically (Xu, 2007b).

- Implementing nonlinear LMSER (Xu, 1991&93). Details are referred to Roadmap B. Here, we add clarifications on two previous confusions. One relates to an omission of the origin of nonlinear LMSER. This has already been clarified in (Karhunen,Pajunen, &Oja,1998; Hyvarinen, Karhunen, & Oja, 2001;Plumbley &Oja,2004), clearly spelling out that the nonlinear $E_2(W)$ and its adaptive gradient rule were both proposed firstly in (Xu, 1991&93). The second confusion is about that ICA is usually regarded as a counterpart of PCA. As stated in (Xu,2001b&03) and observed from the Table in Fig.2, ICA by $y = xW$ is actually an extension of de-correlation analysis, in any combinations of PCs and MCs. The counterpart of MCA is minor ICA (M-ICA) while the counterpart of PCA is principal ICA (P-ICA).

In fact, the concept 'principal' emerges from $e_t = x_t - Ay \neq 0$. As shown within the table in Fig.2 and on the rightmost column on Roadmap B, as $\mathbf{p}(\mathbf{y}_t^{(j)} | \boldsymbol{\mu}^{(j)})$

becomes nonGaussian ones, FA is extended to a binary FA (BFA) if y is binary, and a nonGaussian FA (NFA) if y is real but nonGaussian. Similar to FA performing PCA at $\Sigma_e = \sigma_e^2 I$, both BFA and NFA become to perform a P-ICA at $\Sigma_e = \sigma_e^2 I$.

Observing the first box in this column, for $e_t = x_t - Ay \neq 0$ we need to seek an appropriate nonlinear map $y = f(x)$. It usually has no analytical solution but needs an expensive computation to approximate. As discussed in (Xu, 2003), nonlinear LMSER uses a sigmoid nonlinearity $y_t^{(j)} = s(z_t^{(j)})$, $z = xW$ to avoid computing costs and approximately implements a BFA for a Bernoulli $p(y^{(j)})$ with a probability $p_j = \frac{1}{N} \sum_{t=1}^N s(z_t^{(j)})$ and a NFA for $p(y^{(j)})$ with a pseudo uniform distribution on $(-\infty, +\infty)$, as well as a nonnegative ICA (Plumbley&Oja,2004) when $p(y^{(j)})$ is on $[0, +\infty)$. However, further quantitative analysis is needed for this approximation.

Without approximation, the EM algorithm is developed for maximum likelihood learning since 1997, still suffering expensive computing costs. Favorably, further improvements have also been achieved by the BYY harmony learning. Details are referred to the rightmost column on Roadmap B.

TEMPORAL AND LOCALIZED EXTENSIONS

We further consider temporal samples shown at the bottom of the rightmost column on both Roadmap A and Roadmap B, via embedding a temporal structure in $\mathbf{p}(\mathbf{y}_t^{(j)} | \boldsymbol{\mu}_t^{(j)})$. A typical one is using

$$\boldsymbol{\mu}_t^{(j)} = \boldsymbol{\mu}^{(j)}(\mathbf{Y}_t^{(j)}, \boldsymbol{\varphi}_j), \quad \mathbf{Y}_t^{(j)} = \{\mathbf{y}_{t-\tau}^{(j)}\}_{\tau=1}^{q^{(j)}}$$

e.g., a linear regression

$$\boldsymbol{\mu}_t^{(j)} = \sum_{\tau=1}^{q^{(j)}} \beta_{\tau}^{(j)} \mathbf{y}_{t-\tau}^{(j)},$$

to turn a model (e.g., one in the table of Fig.2) into temporal extensions. Information is carried over time in two ways. One is computing $\boldsymbol{\mu}_t^{(j)}$ by the regression, with learning on $\boldsymbol{\mu}_t^{(j)}$ made through the gradient with respect to \mathbf{J}_j by a chain rule. The second is computing $\int \mathbf{p}(\mathbf{y}_t^{(j)} | \boldsymbol{\mu}_t^{(j)}) \mathbf{p}(\mathbf{Y}_t^{(j)}) d\mathbf{Y}_t^{(j)}$ and getting the gradient with respect to \mathbf{J}_j . Details are referred to Xu (2000&01a&03).

Next, we move to multiple subspaces at different locations as shown in Fig.2. Studies are summarized on Roadmap C, categorized according to one key point, i.e., a scheme $\mathbf{p}_{\ell,t}$ that allocates a sample \mathbf{x}_t to different subspaces. This $\mathbf{p}_{\ell,t}$ bases on two issues.

One is a local measure on how the ℓ -th subspace is suitable for representing \mathbf{x}_t . The other is a mechanism that summarizes the local measures of subspaces to yield $\mathbf{p}_{\ell,t}$. One typical mechanism is that emerges in the EM algorithm for the maximum likelihood or Bayesian learning, where \mathbf{x}_t is fractionally allocated among subspaces proportional to their local measures. Another typical mechanism is that \mathbf{x}_t is nonlinearly located to one or more winners via a competition based on the local measures, e.g., as in the classic competitive learning and the rival penalized competitive learning (RPCL).

Also, a scheme $\mathbf{P}_{\ell,t}$ may come from blending both types of mechanisms, as that from the BYY harmony learning. Details are referred to (Xu,2007c) and its two http-sites.

FUTURE TRENDS

Another important task is how to determine the number \mathbf{k} of subspaces and the dimension \mathbf{m}_{ℓ} of each subspace. It is called model selection, usually implemented in two phases. First, a set of candidates are considered by enumerating \mathbf{k} and \mathbf{m}_{ℓ} , with unknown parameters estimated by the maximum likelihood learning. Second, the best among the candidates is selected by one of criteria, such as AIC, CAIC, SIC/BIC/MDL, Cross Validation, etc. However, this two-phase implementation is computationally very extensive. Moreover, the performance will degenerate considerably when the sample size is finite while \mathbf{k} and \mathbf{m}_{ℓ} are not too small.

One trend is letting model selection to be made automatically during learning, i.e., on a candidate with \mathbf{k} and \mathbf{m}_{ℓ} initially being large enough, learning not only determines unknown parameters but also automatically shrinks \mathbf{k} and \mathbf{m}_{ℓ} to appropriate ones. Two such efforts are RPCL and the BYY harmony learning. Details are referred to (Xu,2007c) and its two http-sites.

Also, there are open issues on $x = Ay + e$, $e \neq 0$, with components of y mutually independent in higher order statistics. Some are listed below:

Figure 5.

| Roadmap C Mixtures of Local Subspaces | | | | | |
|---------------------------------------|--|---|--|---|--|
| Models | | $p(y)$ is Gaussian | | $p(y)$ is nonGaussian | |
| Allocation | | PCA/FA/TFA | MCA/Surface fitting | ICA | NFA/BFA/LMSER and temporal extensions |

- Which part of unknown parameters in $x = Ay + e$ can be determined uniquely ?
- Under which conditions, the independence

$$p(y) = \prod_{j=1}^m p(y^{(j)})$$

can be ensured in concept? Can it be further achieved by a learning algorithm?

- In what a sense, both ensuring

$$p(y) = \prod_{j=1}^m p(y^{(j)})$$

and the best reconstruction of x by $\hat{x} = Ay$ can be achieved simultaneously? If not, what is the best nonlinear $y = f(x)$ in term of both

$$p(y) = \prod_{j=1}^m p(y^{(j)})$$

and $e \neq 0$?

- Can such a best be obtained analytically or via an effective computing?

CONCLUSION

Studies of three closely related unsupervised learning streams have been overviewed in an extensive scope

and from a systematic perspective. A general framework of independent subspaces is presented, from which a number of learning topics are summarized via different features of choosing and combining the three basic ingredients.

KEY TERMS

BYY Harmony Learning: It is a statistical learning theory for a two pathway featured intelligent system via two complementary Bayesian representations of the joint distribution on the external observation and its inner representation, with both parameter learning and model selection determined by a principle that two Bayesian representations become best harmony. See http://www.scholarpedia.org/article/Bayesian_Ying_Yang_Learning.

Factor Analysis: A set of samples $\{\mathbf{x}_t\}_{t=1}^N$ is described by a linear model $x = Ay + \mu + e$, where μ is a constant, y and e are both from Gaussian and mutually uncorrelated, and components of y are called factors and mutually uncorrelated. Typically, the model is estimated by the maximum likelihood principle.

Independence Subspaces: It refers to a family of models, each of which consists of one or several subspaces. Each subspace is spanned by linear independent

basis vectors and the corresponding coordinates are mutually independent.

Least Mean Square Error Reconstruction (LM-SER): For an orthogonal projection x_t onto a subspace spanned by the column vectors of a matrix W , maximizing $\frac{1}{N} \sum_{t=1}^N (\mathbf{w}^T \mathbf{x}_t)^2$ subject to $\mathbf{w}^T \mathbf{w} = 1$ is equivalent to minimizing the mean square error $\frac{1}{N} \sum_{t=1}^N \|\mathbf{x}_t - \hat{\mathbf{x}}_t\|^2$ by using the projection $\hat{\mathbf{x}}_t = \mathbf{W} \mathbf{W}^T \mathbf{x}_t$ as reconstruction of x_t , which is reached when W spans the same subspace spanned by the PCs.

Minor Component (MC): Being orthogonal complementary to the PC, the solution of $\min_{(\mathbf{w}^T \mathbf{w}=1)} \mathbf{J}(\mathbf{w}) = \frac{1}{N} \sum_{t=1}^N (\mathbf{w}^T \mathbf{x}_t)^2 = \mathbf{w}^T \Sigma \mathbf{w}$ is the MC, while the m-MCs are referred to the columns of W that minimizes $\mathbf{J}(W) = \frac{1}{N} \sum_{t=1}^N \|W^T \mathbf{x}_t\|^2 = \text{Tr}[W^T \Sigma W]$ subject to $\mathbf{w}^T \mathbf{w} = 1$.

Principal Component (PC): For samples $\{\mathbf{x}_t\}_{t=1}^N$ with a zero mean, its PC is a unit vector \mathbf{w} originated at zero with a direction along which the average of the orthogonal projection by every sample is maximized, i.e., $\max_{(\mathbf{w}^T \mathbf{w}=1)} \mathbf{J}(\mathbf{w}) = \frac{1}{N} \sum_{t=1}^N (\mathbf{w}^T \mathbf{x}_t)^2 = \mathbf{w}^T \Sigma \mathbf{w}$, the solution is the eigenvector of the sample covariance matrix $\Sigma = \frac{1}{N} \sum_{t=1}^N \mathbf{x}_t \mathbf{x}_t^T$, corresponding to the largest eigen-value. Generally, the m-PCs are referred to the m orthonormal vectors as the columns of W that maximizes $\mathbf{J}(W) = \frac{1}{N} \sum_{t=1}^N \|W^T \mathbf{x}_t\|^2 = \text{Tr}[W^T \Sigma W]$.

Rival Penalized Competitive Learning: It is a development of competitive learning in help of an appropriate balance between participating and leaving mechanisms, such that an appropriate number of agents or learners will be allocated to learn multiple structures underlying observations. See http://www.scholarpedia.org/article/Rival_Penalized_Competitive_Learning.

Total Least Square (TLS) Fitting: Given samples $\{\mathbf{z}_t\}_{t=1}^N$, $\mathbf{z}_t = [\mathbf{y}_t, \mathbf{x}_t^T]^T$, instead of finding a vector \mathbf{w} to minimize the error $\frac{1}{N} \sum_{t=1}^N \|\mathbf{y}_t - \mathbf{w}^T \mathbf{x}_t\|^2$, the TLS fitting is finding an augmented vector $\tilde{\mathbf{w}} = [\mathbf{w}^T, c]^T$ such that the error $\frac{1}{N} \sum_{t=1}^N \|\tilde{\mathbf{w}}^T \mathbf{z}_t\|^2$ is minimized subject to $\tilde{\mathbf{w}}^T \tilde{\mathbf{w}} = 1$, the solution is the MC of $\{\mathbf{z}_t\}_{t=1}^N$.

Information Theoretic Learning

INTRODUCTION

Learning systems depend on three interrelated components: topologies, cost/performance functions, and learning algorithms. Topologies provide the constraints for the mapping, and the learning algorithms offer the means to find an optimal solution; but the solution is optimal with respect to what? Optimality is characterized by the criterion and in neural network literature, this is the least addressed component, yet it has a decisive influence in generalization performance. Certainly, the assumptions behind the selection of a criterion should be better understood and investigated.

Traditionally, least squares has been the benchmark criterion for regression problems; considering classification as a regression problem towards estimating class posterior probabilities, least squares has been employed to train neural network and other classifier topologies to approximate correct labels. The main motivation to utilize least squares in regression simply comes from the intellectual comfort this criterion provides due to its success in traditional linear least squares regression applications – which can be reduced to solving a system of linear equations. For nonlinear regression, the assumption of Gaussianity for the measurement error combined with the maximum likelihood principle could be emphasized to promote this criterion. In nonparametric regression, least squares principle leads to the conditional expectation solution, which is intuitively appealing. Although these are good reasons to use the mean squared error as the cost, it is inherently linked to the assumptions and habits stated above. Consequently, there is information in the error signal that is not captured during the training of nonlinear adaptive systems under non-Gaussian distribution conditions when one insists on second-order statistical criteria. This argument extends to other linear-second-order techniques such as principal component analysis (PCA), linear discriminant analysis (LDA), and canonical correlation

analysis (CCA). Recent work tries to generalize these techniques to nonlinear scenarios by utilizing kernel techniques or other heuristics. This begs the question: *what other alternative cost functions could be used to train adaptive systems and how could we establish rigorous techniques for extending useful concepts from linear and second-order statistical techniques to nonlinear and higher-order statistical learning methodologies?*

BACKGROUND

This seemingly simple question is at the core of recent research on information theoretic learning (ITL) conducted by the authors, as well as research by others on alternative optimality criteria for robustness to outliers and faster convergence, such as different L_p -norm induced error measures (Sayed, 2005), the epsilon-insensitive error measure (Scholkopf & Smola, 2001), Huber's robust m-estimation theory (Huber, 1981), or Bregman's divergence based modifications (Bregman, 1967). Entropy is an uncertainty measure that generalizes the role of variance in Gaussian distributions by including information about the higher-order statistics of the probability density function (pdf) (Shannon & Weaver, 1964; Fano, 1961; Renyi, 1970; Csiszár & Körner, 1981). For on-line learning, information theoretic quantities must be estimated nonparametrically from data. A nonparametric expression that is differentiable and easy to approximate stochastically will enable importing useful concepts such as stochastic gradient learning and backpropagation of errors. The natural choice is kernel density estimation (KDE) (Parzen, 1967), due its smoothness and asymptotic properties. The plug-in estimation methodology (Gyorfi & van der Meulen, 1990) combined with definitions of Renyi (Renyi, 1970), provides a set of tools that are well-tuned for learning applications – tools suitable

for supervised and unsupervised, off-line and on-line learning. Renyi's definition of entropy for a random variable X is

$$H_{\alpha}(X) = \frac{1}{1-\alpha} \log \int p^{\alpha}(x) dx \quad (1)$$

This generalizes Shannon's linear additivity postulate to exponential additivity resulting in a parametric family. Dropping the logarithm for optimization simplifies algorithms. Specifically of interest is the quadratic entropy ($\alpha=2$), because its sample estimator requires only one approximation (the density estimator itself) and an analytical expression for the integral can be obtained for kernel density estimates. Consequently, a sample estimator for quadratic entropy can be derived for Gaussian kernels of standard deviation σ on an iid sample set $\{x_1, \dots, x_N\}$ as the sum of pairwise sample (particle) interactions (Principe et al, 2000):

$$\hat{H}_2(X) = -\log\left(\frac{1}{N^2} \sum_{i=1}^N \sum_{j=1}^N G_{\sqrt{2}\sigma}(x_i - x_j)\right) \quad (2)$$

The pairwise interaction of samples through the kernel intriguingly provides a connection to entropy of particles in physics. Particles interacting through *information forces* (as in the N -body problem in physics) can employ computational techniques developed for simulating such large scale systems. The use of entropy in training multilayer structures can be studied in the backpropagation of information forces framework (Erdogmus et al, 2002). The quadratic entropy estimator was employed in measuring divergences between probability densities and blind source separation (Hild et al, 2006), blind deconvolution (Lazaro et al, 2005), and clustering (Jenssen et al, 2006). Quadratic expressions with mutual-information-like properties were introduced based on the Euclidean and Cauchy-Schwartz distances (ED/CSD). These are advantageous with computational simplicity and statistical stability in optimization (Principe et al, 2000).

Following the conception of information potential and force and principles, the pairwise-interaction estimator is generalized to use arbitrary kernels and any order α of entropy. The stochastic information gradient (SIG) is developed (Erdogmus et al, 2003) to train adaptive systems with a complexity comparable

to the LMS (least-mean-square) algorithm - essential for training complex systems with large data sets. Supervised and unsupervised learning is unified under information-based criteria. Minimizing error entropy in supervised regression or maximizing output entropy for unsupervised learning (factor analysis), minimization of mutual information between the outputs of a system to achieve independent components or maximizing mutual information between the outputs and the desired responses to achieve optimal subspace projections in classification is possible. Systematic comparisons of ITL with conventional MSE in system identification verified the advantage of the technique for nonlinear system identification and blind equalization of communication channels. Relationships with instrumental variables techniques were discovered and led to the error-whitening criterion for unbiased linear system identification in noisy-input-output data conditions (Rao et al, 2005).

SOME IDEAS IN AND APPLICATIONS OF ITL

Kernel Machines and Spectral Clustering: KDE has been motivated by the smoothness properties inherent to reproducing kernel Hilbert spaces (RKHS). Therefore, a practical connection between KDE-based ITL, kernel machines, and spectral machine learning techniques was imminent. This connection was realized and exploited in recent work that demonstrates an information theoretic framework for pairwise similarity (spectral) clustering, especially normalized cut techniques (Shi & Malik, 2000). Normalized cut clustering is shown to determine an *optimal* solution that maximizes the CSD between clusters (Jenssen, 2004). This connection immediately allows one to approach kernel machines from a density estimation perspective, thus providing a robust method to select the *kernel size*, a problem still investigated by some researchers in the kernel and spectral techniques literature. In our experience, kernel size selection based on suitable criteria aimed at obtaining the *best* fit to the training data - using Silverman's regularized squared error fit (Silverman, 1986) or leave-one-out cross-validation maximum likelihood (Duin, 1976), for instance - has proved to be convenient, robust, and accurate techniques that avoid many of the computational complexity and load

issues. Local data spread based modifications resulting in variable-width KDE are also observed to be more robust to noise and outliers.

An illustration of ITL clustering by maximizing the CSD between the two estimated clusters is provided in Figure 1. The samples are labeled to maximize

$$D_{CS}(p, q) = -\log \frac{\langle p, q \rangle_f}{\|p\|_f \|q\|_f} \quad (3)$$

where p and q are KDE for two candidate clusters, f is the overall data KDE and the weighted inner product to measure angular distance between clusters is

$$\langle p, q \rangle_f = \int p(x)q(x)f^{-1}(x)dx \quad (4)$$

When estimated using a weighted KDE variant, this criterion becomes equivalently

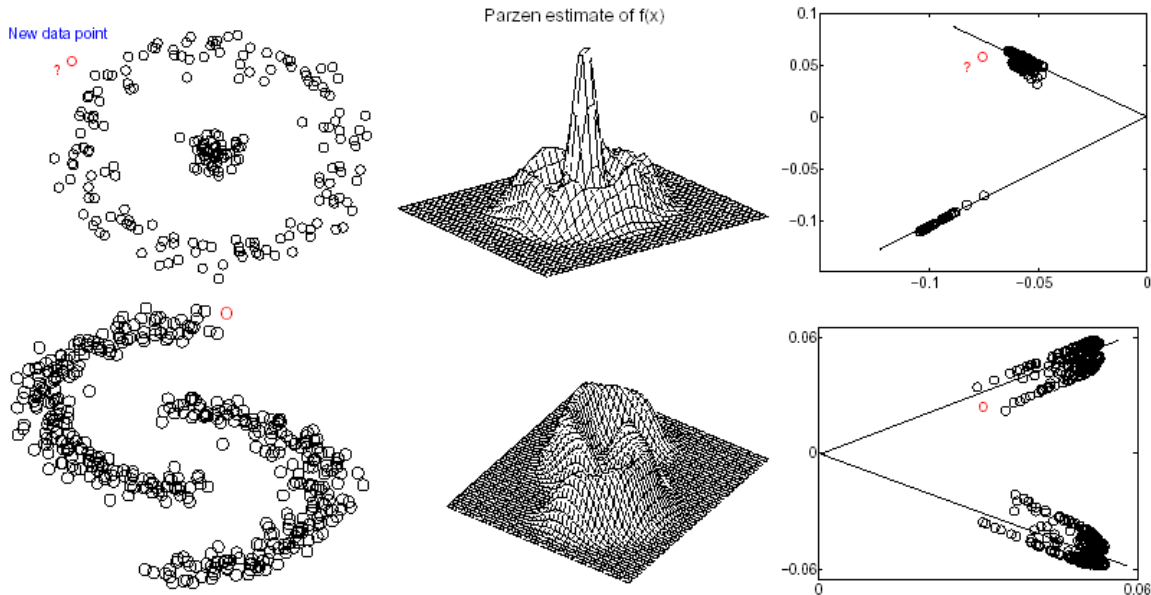

$$D_{CS}(p, q) \approx \frac{\sum_{x_i \in p, y_j \in q} K_{1/f}(x_i, y_j)}{\sqrt{\sum_{x_i \in p, x_j \in p} K_{1/f}(x_i, x_j) \sum_{y_i \in q, y_j \in q} K_{1/f}(y_i, y_j)}} \quad (5)$$

where $K_{1/f}$ is an equivalent kernel generated from the original kernel K (Gaussian here). One difficulty with kernel machines is their nonparametric nature, the requirement to solve for the eigendecomposition of a large positive-definite matrix that has size $N \times N$, for N training samples. The solution is a weighted sum of kernels evaluated over each training sample, thus the test procedure for each novel sample involves evaluating the sum of N kernels: $y_{test} = \sum_{k=1}^N w_k K(x_{test} - x_k)$. The Fast Gauss Transform (FGT) (Greengard, 1991), which uses the polynomial expansions for a Gaussian (or other) kernel has been employed to overcome this difficulty. FGT carefully selects few center points around which truncated Hermite polynomial expansions approximate the kernel machine. FGT still requires heavy computational load in off-line training (minimum $O(N^2)$, typically $O(N^3)$). The selection of expansion centers is typically done via clustering (e.g., Ozertem & Erdogmus, 2006).

Correntropy as a Generalized Similarity Metric:

The main feature of ITL is that it preserves the universe of concepts we have in neural computing, but allows the adaptive system to *extract more information* from the data. For instance, the general Hebbian principle is

Figure 1. Maximum CSD clustering of two synthetic benchmarks: training and novel test data (left), KDE using Gaussian kernels with Silverman-kernel-size (center), and spectral projections of data on two dominant eigenfunctions of the kernel. The eigenfunctions are approximated using the Nystrom formula.

reduced into a second order metric in traditional artificial neural network literature (input-output product), thus becoming a synonym for second order statistics. The learning rule that maximizes output entropy (instead of output variance), using SIG with Gaussian kernels is $\Delta w(n) = \eta(x(n) - x(n-1))(y(n) - y(n-1))$ (Erdogmus et al, 2002), which still obeys the Hebbian principle, yet extracts more information from the data (leading to the error-whitening criterion for input-noise robust learning).

ITL quantifies global properties of the data, but will it be possible to apply it to functions, specifically those in RKHS? A concrete example is on similarity between random variables, which is typically expressed as second order correlation. Correntropy generalizes similarity to include higher order moment information. The name indicates the strong relation to correlation, but also stresses the difference – the average over the lags (for random processes) or over dimensions (for multidimensional random variables) is the information potential, i.e. the argument of second order Renyi's entropy. For random variables X and Y with joint density $p(x,y)$, correntropy is defined as

$$V(X,Y) = \int \int \delta(x-y) p(x,y) dx dy \quad (6)$$

and measures how dense the two random variables are along the line $x=y$ in the joint space. Notice that it is similar to correlation, which also asks the same question in a second moment framework. However, correntropy is local to the line $x=y$, while correlation is quadratically dependent upon distances of samples in the joint space. Using a KDE with Gaussian kernels

$$V(X,Y) = \frac{1}{N} \sum_{i=1}^N G(x_i - y_i) \quad (7)$$

Correntropy is a positive-definite function, thus defines a RKHS. Unlike correlation, RKHS is nonlinearly related to the input, because all moments of the random variable are included in the transformation. It is possible to analytically solve for least squares regression and principal components in this space, yielding nonlinear fits in input space. Correntropy induced metric (CIM) behaves as the L_2 -norm for small distances and progressively approaches the L_1 -norm and then converges to L_0 at infinity. Thus robustness to outliers is automatically achieved and equivalence to Huber's robust estimation can be proven (Santamaria, 2006). Unlike conventional kernel methods, correntropy solutions remain in the same dimensionality as the in-

Figure 2. Maximum mutual information projection versus kernel LDA test ROC results on hand-written digit recognition shown in terms of type-1 and type-2 errors (left); ROC results (P_{detect} vs P_{false}) compared for various techniques on sonar data. Both data are from the UCI Machine Learning Repository (2007).

put vector. This might indicate built-in regularization properties, yet to be explored.

Nonparametric Learning in the RKHS: It is possible to obtain robust solutions to a variety of problems in learning using the nonparametric and local nature of KDE and its relationship with RKHS theory. Recently, we explored the possibility of designing nonparametric solutions to the problem of identifying nonlinear dimensionality reduction schemes that maintain maximal discriminative information in a pattern recognition problem (quite appropriately measured by the mutual information between the data and the class labels as agreed upon by many researchers). Using the RKHS formalism and based on the KDE, results were obtained that consistently outperformed the alternative rather heuristic kernel approaches such as kernel PCA and kernel LDA (Scholkopf & Smola, 2001). The conceptual oversight in the latter two is that, both PCA and LDA procedures are most appropriate for Gaussian distributed data (although acceptable for other symmetric unimodal distributions and are commonly but possibly inappropriately used for arbitrary data distributions).

Clearly, the distribution of the data in the kernel induced feature space could not be Gaussian for all typically exploited kernel selections (such as the Gaussian kernel), since these are usually translation invariant, therefore the data is, in principle, mapped to an infinite dimensional hypersphere on which the data could not

have been Gaussian distributed (nor symmetrically distributed in general for the ideal kernel for a given problem since these are positive definite functions). Consequently, the hasty use of kernel extensions of second-order techniques is not necessarily optimal in a meaningful statistical sense. Nevertheless, these techniques have found *successful* applications in various problems; however, their suboptimality is clear from comparisons with more carefully designed solutions. In order to illustrate how drastic the performance difference could be, we present a comparison of a mutual information based nonlinear nonparametric projection approach (Ozertem et al, 2006) and kernel LDA in a simplified two-class handwritten digit classification case study and sonar mine detection case study. The ROC curves of both algorithms on the test set after being trained with the same data is shown in Figure 2. The kernel is assumed to be a circular Gaussian with size set to Silverman's rule-of-thumb. For the sonar data, we also include KDE-based approximate Bayes classifier and linear LDA for reference. In this example, KLDA performs close to mutual information projections, as observed occasionally.

FUTURE TRENDS

Nonparametric Snakes, Principal Curves and Surfaces: More recently, we have been investigating

Figure 3. Nonparametric snake after convergence from an initial state that was located at the boundary of the guitar image rectangle (left). The global principal curve of a mixture of ten Gaussians obtained according to the local subspace maximum definition for principal manifolds (right).

the application of KDE and RKHS to nonparametric clustering, principal curves and surfaces. Interesting mean-shift-like fixed-point algorithms have been obtained; specifically interesting is the concepts of *nonparametric snakes* (Ozertem & Erdogmus, 2007) and *local principal manifolds* (Erdogmus & Ozertem, 2007) that we developed recently. The nonparametric snake approach overcomes the principal difficulties experienced by snakes (active contours) for image segmentation, such as low capture range, data curvature inhomogeneity, and noisy and missing edge information. Similarly, the local conditions for determining whether a point is in a principal manifold or not provide guidelines for designing fixed point and other iterative learning algorithms for identifying such important structures.

Specifically in nonparametric snakes, we treat the edgemap of an image as samples and the values of the edginess as weights to construct a weighted KDE, from which, a fixed point iterative algorithm can be devised to detect the boundaries of an object in background. The designed algorithm can be easily made robust to outlier edges, converges very fast, and can penetrate into concavities, while not being trapped into the object at missing edge localities. The guitar image in Figure 3 emphasizes these advantages as the image exhibits both missing edges and concavities, while background complexity is trivially low as that was not the main concern in this experiment – the variable width KDE easily avoids textured obstacles. The algorithm could be utilized to detect the ridge-boundary of a structure in any dimensional data set in other applications.

In defining principal manifolds, we avoided the traditional least-squares error reconstruction type criteria, such as Hastie's self-consistent principal curves (Hastie & Stuetzle, 1989), and proposed a local subspace maximum definition for principal manifolds inspired by differential geometry. This definition lends itself to a uniquely defined principal manifold hierarchy such that one can use inflation and deflation to obtain a d -dimensional principal manifold from a $(d+1)$ -dimensional principal manifold. The rigorous and local definition lends itself to easy algorithm design and multiscale principal structure analysis for probability densities. We believe that in the near future, the community will be able to prove maximal information preserving properties of principal manifolds obtained using this definition in a manner similar to mean-shift clustering

solving for minimum information distortion clustering (Rao et al, 2006) and maximum likelihood modelling achieving minimum Kullback-Leibler divergence asymptotically (Carreira-Perpinan & Williams, 2003; Erdogmus & Principe, 2006).

CONCLUSION

The use of information theoretic learning criteria in neural networks and other adaptive system solutions have so far clearly demonstrated a number of advantages that arise due to the increased information content of these measures relative to second-order statistics (Erdogmus & Principe, 2006). Furthermore, the use of kernel density estimation with smooth kernels allows one to obtain continuous and differentiable criteria suitable for iterative descent/ascent-based learning and the nonparametric nature of KDE and its variants (such as variable-size kernels) allow one to achieve simultaneously robustness, global optimization through *kernel annealing*, and data modeling flexibility in designing neural networks and learning algorithms for a variety of benchmark problems. Due to lack of space, detailed mathematical treatments cannot be provided in this article; the reader is referred to the literature for details.

KEY TERMS

Cauchy-Schwartz Distance: An angular density distance measure in the Euclidean space of probability density functions that approximates information theoretic divergences for nearby densities.

Correntropy: A statistical measure that estimates the similarity between two or more random variables by integrating the joint probability density function along the main diagonal of the vector space (line along ones). It relates to Renyi's entropy when averaged over sample-index lags.

Information Theoretic Learning: A technique that employs information theoretic optimality criteria such as entropy, divergence, and mutual information for learning and adaptation.

Information Potentials and Forces: Physically intuitive pairwise particle interaction rules that emerge from information theoretic learning criteria and govern the learning process, including backpropagation in multilayer system adaptation.

Kernel Density Estimate: A nonparametric technique for probability density function estimation.

Mutual Information Projections: Maximally discriminative nonlinear nonparametric projections for feature dimensionality reduction based on the reproducing kernel Hilbert space theory.

Renyi Entropy: A generalized definition of entropy that stems from modifying the additivity postulate and results in a class of information theoretic measures that contain Shannon's definitions as special cases.

Stochastic Information Gradient: Stochastic gradient of nonparametric entropy estimate based on kernel density estimation.

INTRODUCTION

This chapter is focused on the analysis and classification of arrhythmias. An arrhythmia is any cardiac pace that is not the typical sinusoidal one due to alterations in the formation and/or transportation of the impulses. In pathological conditions, the depolarization process can be initiated outside the sinoatrial (SA) node and several kinds of extra-systolic or ectopic beatings can appear.

Besides, electrical impulses can be blocked, accelerated, deviated by alternate trajectories and can change its origin from one heart beat to the other, thus originating several types of blockings and anomalous connections. In both situations, changes in the signal morphology or in the duration of its waves and intervals can be produced on the ECG, as well as a lack of one of the waves.

This work is focused on the development of intelligent classifiers in the area of biomedicine, focusing on the problem of diagnosing cardiac diseases based on the electrocardiogram (ECG), or more precisely on the differentiation of the types of atrial fibrillations. First of all we will study the ECG, and the treatment

of the ECG in order to work with it, with this specific pathology. In order to achieve this we will study different ways of elimination, in the best possible way, of any activity that is not caused by the auriculars. We will study and imitate the ECG treatment methodologies and the characteristics extracted from the electrocardiograms that were used by the researchers that obtained the best results in the Physionet Challenge, where the classification of ECG recordings according to the type of Atrial Fibrillation (AF) that they showed, was realised. We will extract a great amount of characteristics, partly those used by these researchers and additional characteristics that we consider to be important for the distinction mentioned before. A new method based on evolutionary algorithms will be used to realise a selection of the most relevant characteristics and to obtain a classifier that will be capable of distinguishing the different types of this pathology.

BACKGROUND

The electrocardiogram (ECG) is a diagnostic tool that measures and records the electrical activity of the heart

in exquisite detail (Lanza 2007). Interpretation of these details allows diagnosis of a wide range of heart conditions. The QRS complex is the most striking waveform within the electrocardiogram (Figure 1). Since it reflects the electrical activity within the heart during the ventricular contraction, the time of its occurrence as well as its shape provide much information about the current state of the heart. Due to its characteristic shape

it serves as the basis for the automated determination of the heart rate, as an entry point for classification schemes of the cardiac cycle, and often it is also used in ECG data compression algorithms.

A normal QRS complex is 0.06 to 0.10 sec (60 to 100 ms) in duration. In order to have a signal clean of auricular activity in the ECG, we will analyse and compare performances from these two different approaches:

1. To remove the activity of the QRS complex, subtracting from the signal a morphological average of its activity for every heart beat,
2. To detect the TQ section among heart beats (which are zones clean of ventricular activity) and analyse only data from that section.

Figure 1. Diagram of the QRS complex

There exists a great variety of algorithms to carry out the extraction of the auricular activity from the electrocardiogram such as the Thakor method (a recurrent adaptive filter structure), adaptive filtering of the whole band, methods based on neural-networks, spatial-temporal cancellation methods and methods based on Wavelets or on the concept of Principal Component Analysis (PCA) (Castells et al. 2004, Gilad-Bachrach et al. 2004, Petrutiu et al. 2004).

A fundamental step in any of these approaches is the detection of the QRS complex in every heart beat. Software QRS detection has been a research topic for

Figure 2. The segments are shown detected by the algorithm on the two channels of a registration. In green the end of the wave T is shown, and in red the principle of the wave Q. Therefore each tract among final of wave T (green) and wave principle Q (red), it is a segment of auricular activity. The QRST complex is automatically detected with good precision.

more than 30 years. Once the QRS complex is identified, we will have a starting point to implement some different techniques for the QRST removal. Figure 2 show how the QRST is automatically detected. This is the first step in the analysis of the ECG.

The study and analysis of feature extraction techniques from ECG signals is a very common task in any implementation of automatic classification systems from signals of any kind. During the execution of this sub-task, it is very important to analyse different research results existing in the literature.

It is important to analyse the use of the frequency domain to obtain the Dominant Atrial Frequency (DAF) which is an index of the auricular activity which measures the dominant frequency in the frequency spectrum that can be obtained from the auricular activity signal. In this spectrum, for each ECG record, the maximum energy peak is calculated, and this frequency will be the one that dominates the spectrum (Cantini et al. 2004). It is also important to use the RR distance, and different filters in the 4-10Hz range, using a Butterworth filter of first order. It is important to note the MUSIC (Multiple Signal Classification) method of order 12 to calculate the pseudo-periodogram of the signal. In order to obtain more robust estimations, signal filtering by variable-length windows, with no overlapping, and on every one of them, an analysis of the frequency spectrum can be performed. It is also important to note the Welch method, the Choi-Williams transform, and some heuristical methods used by cardiology experts (Atrial Fibrillation, 2007).

GENETIC PROGRAMMING

The genetic programming (GP) can be understood as an extension of the genetic algorithm (GA) (Zhao, 2007). GP began as an attempt to discover how computers could learn to solve problems, in different fields, like automatic desing, function approximation, classification, robotic control, signal processing, without being explicitly programmed to do so (Koza, 2003). Also, in bio-medical application, GP has been extensively and satisfactorily used (Lopes, 2007). The primary differences between GAS and GP can be summarised as a) GP typically codes solutions as tree structured, variable length chromosomes, while GA's generally make use of chromosomes of fixed length and structure, b) GP typically incorporates a domain specific syntax that

governs acceptable (or meaningful) arrangements of information on the chromosome. For GA's, the chromosomes are typically syntax free.

The field of program induction, using a tree-structured approach, was first clearly defined by Koza (Koza, 2003). The following steps summarise the search procedure used with GP.

1. Create an initial population of programs, randomly generated as compositions of the function and terminal sets.
2. WHILE termination criterion not reached DO
 - (a) Execute each program to obtain a performance (fitness) measure representing how well each program performs the specified task.
 - (b) Use a fitness proportionate selection method to select programs for reproduction to the next generation.
 - (c) Use probabilistic operators (crossover and mutation) to combine and modify components of the selected programs.
3. The fittest program represents a solution to the problem.

A NEW INTELLIGENT CLASSIFIER BASED ON GENETIC PROGRAMMING FOR ECG.

In the different articles we have studied, the authors did not use any algorithmic method in order to try to classify the electrocardiograms (Cantini et al. 2004, Lemay et al. 2004). The authors applied simple methods to try to establish the possible classification based on the classification capacity of one single characteristic or pairs of characteristics (through a graphic representation) (Hay et al. 2004). Nevertheless, the fact that one single characteristic might not be perfect individually to classify a group of patterns in the different categories, does not mean that combined with another or others it does not obtain some high percentages in the classification. Due to the great quantity of characteristics obtained from the ECG, a method to classify the patterns was needed, alongside a way of selecting the subgroup of characteristics optimal for classifying, since the great quantity of existing characteristics would introduce noise as soon as the search for the optimal classifier of the patterns of characteristics begins. In total 55 different

characteristics were used, from the papers (Cantini et al. 2004, Lemay et al. 2004, Hayn et al. 2004, Mora et al. 2004). There are other paper in the bibliography that used soft-computing method to analyze ECG (Wiggins et al. 2008, Lee et al. 2007, Yu et al. 2007).

In this paper, a new intelligent algorithm based on genetic programming (one paradigm of the soft-computing area) for simultaneously select the best features is proposed for the problem of classification spontaneous termination of atrial fibrillation. In this algorithm genetic programming is used to search for a good classifier at the same time as the search for an optimal subgroup of characteristics. The algorithm consists of a population of classifiers, and each one of those is associated with a fitness value that indicates how well it classifies. Each classifier is made up of:

1. A binary vector of characteristics, which indicates with 1's the characteristics it uses.
2. A multitree with as many trees as classes as has the collection of data of the problem. Every tree i distinguishes between the class i (giving a positive output) and the rest of the classes (negative output). Furthermore, it is connected to values p_j (frequency of failures), and w_j (frequency of successes). The trees are made up of function nodes [$+$, $-$, $*$, $/$, trigonometric functions (sine, cosine, etc.), statistic functions (minimums, maximums, average)] and terminal nodes {constant number and features}. Their translation to a mathematical formula is immediate.

The algorithm consists of a loop in which in each repetition a new population is formed from the previous through the genetic operators. The classifiers that score the highest on fitness will have more possibilities to participate, with which the population will tend to improve its quality with the successive generations. The proposed algorithm is composed of the following building blocks:

1. **Fitness function.** The fitness function combines the double objective of achieving a good classification and a small subgroup of characteristics:

$$Fitness = f \cdot \left(1 + \alpha e^{-\frac{\beta}{n}} \right) \quad (1)$$

In this equation, f is the sum of the cases of success in the classification of the trees, β is the cardinality of the feature subset used, n is the total number of features and α is a parameter which determines the relative importance that we want to assign for correct classification and the size of the feature subset, calculated as:

$$\alpha = C \left(1 - \frac{gen}{TotalGen} \right) \quad (2)$$

where C is a constant, and $TotalGen$ is the number of generations proposed genetic algorithm is evolved, and gen is the current generation number.

Figure 3. An example of a crossover operation in the proposed multitree classifier. (a) and (b) are initially the classifiers P1 and P2. In the figures (c) and (d) the results of the crossover operator is presented.

2. **Reproduction operator:** a classifier chosen proportionally to the fitness passes on, intact, to the next generation.
3. **Mutation operator:** a classifier is selected randomly and nodes of a tree are changed, giving more probability to the worst trees.
4. **Crossover operator:** homogeneous cross (classifiers with the same characteristics) and heterogeneous cross (classifiers with a similar subgroup). It realises the exchange of subtrees and trees between the classifiers. Figure 3 shows the behaviour of this operator.

It was thought to be useful to value the characteristics first, and use this assessment when a subgroup would be assigned to the classifier. This is performed in the following steps:

- A probability is given to each characteristic of being assigned to the initial subgroup of the classifier proportional to its assessment.
- G-flip was used to assess the characteristics (Gilad-Bacharach et al. 2004). G-flip is a greedy search algorithm for maximizing an evaluation function that take into account the number of features selected. The algorithm repeatedly iterates over the feature set and updates the set of chosen features. In each iteration it decides to remove or add the current feature to the selected set by evaluating the margin term of the evaluation function with and without this feature. This algorithm is similar

to the zero-temperature Monte-Carlo (Metropolis) method. It converges to a local maximum of the evaluation function, as each step increases its value and the number of possible feature sets is finite.

- The proposed methodology devalues bad characteristics in groups with a large quantity of characteristics, thus accelerating their convergence to good groups of characteristics and good classification results.

SIMULATION RESULTS

We have used and compared two different new intelligent classifiers. The first one presents an online feature selection algorithm using genetic programming. The proposed genetic programming methodology simultaneously selects a good subset of features and constructs a classifier using the selected features for the problem of ECG classification. We have designed new genetic operator in order to produce a robust and precise algorithm. The other classifier is based in the hybridization of a feature selection algorithm and a neural network system based on kernel method (Support Vector Machine).

We have four classification task:

- ✓ Event A: To differ among registration N (Group N: non-terminating AF -defined as AF that was not observed to have terminated for the duration

Table 1. Comparison of different approaches (in bracket the standard deviation)

| Method: | Infogain (Molina et al. 2002) | | New evolutive algorithm for classification | | Kernel method (Support Vector Machine) (Schölkopf et al. 2002) | | Relief (Kononenko 1994) | |
|----------|-------------------------------------|--------------------|--|-----------------|--|-----------------|----------------------------|----------------|
| Task | Best | Median/ (error) | Best | Median | Best | Median | Best | Median |
| Event A: | 93 | 91 (± 2) | 100 | 98 (± 2) | 100 | 98 (± 2) | 72 | 64 (± 8) |
| Event B: | 70 | 66 (± 4) | 95 | 81 (± 14) | 80 | 68 (± 12) | 80 | 74 (± 6) |
| Event C: | 96 | 88 (± 6) | 89 | 83 (± 6) | 84 | 75 (± 9) | 74 | 68 (± 6) |
| Event D: | 68 | 62 (± 4) | 85 | 80 (± 5) | 83 | 77 (± 6) | 53 | 49 (± 4) |

of the long-term recording, at least an hour following the segment-) and registration T (Group T: AF that terminates immediately (within one second) after the end of the record).

- ✓ Event B: To differ among the type registrations S (Group S: AF that terminates one minute after the end of the record) and those of type T.
- ✓ Event C: To differ among registrations type N of AF and a second group in which registrations type S and type T are included.
- ✓ Event D: Separation of the 3 types of registrations in a simultaneous way.

These groups N, T and S are distributed across a learning set (consisting of 10 labelled records from each group) and two test sets. Test set A contains 30 records, of which about one-half are from group N, and of which the remainder are from group T. Test set B contains 20 records, 10 from each of groups S and T. Table 1 shows the simulation results (in % of classification), for different method and the evolutive algorithm proposed for ECG classification:

FUTURE TRENDS

The field of signal processing in bio-medical problems is an exciting and increasingly field nowadays. The rapid development of powerful microcomputers promoted the widespread application of software for electrocardiogram analysis and QRS detection algorithms in cardiological devices, and automatic classifiers.

However, and important research field for the next year, will be the hybridization of new intelligent techniques, as genetic algorithm and genetic programming, or other paradigms from soft-computing (fuzzy logic, neural networks, SVM, etc.), that improve the behaviour of standard classification algorithm for the diagnosis of different cardiological pathologies.

CONCLUSIONS

In this paper, a new online feature selection algorithm using genetic programming technique has been proposed as classifier for classification spontaneous termination of atrial fibrillation. In a combined way, our genetic programming methodology automatically

selects the required features while design the multitree classifier.

Different genetic operator has been design for the multitree classifier, and for a better performance of the classifier, the initialization process generates solution using smaller feature subsets with has been previously selected with a greedy search algorithm (G-Flips) for maximizing the evaluation function. The effectiveness of the proposed scheme is demonstrated in a real problem: The Classification Spontaneous Termination of Atrial Fibrillation. At this point, it is important to note that the use of different characteristic gives different classification result as can be observed by the authors working in this challenge. The selection of different features extracted from an electrocardiogram has a strong influence on the problem to be solve and in the behaviour of the classifier. Therefore it is important to develop a general tool able to be face with different cardiac illnesses, which can select the most appropriate features in order to obtain an automatic classifier. As it can be observed, the proposed methodology has very good result compared with the winner of the challenge from PhysioNet and Computers in Cardiology 2004, even if this methodology has been developed in a general way to resolved different classification problems.

KEY TERMS

Arrhythmia: Arrhythmias are disorders of the regular rhythmic beating of the heart. Arrhythmias can be divided into two categories: ventricular and supraventricular.

Atrial Fibrillation: The atrial fibrillation (AF) is the sustained arrhythmia that is most frequently found in clinical practice, present in 0.4% of the total population. Its frequency increases with age and with the presence of structural cardiopathology. AF is especially prevalent in the elderly, affecting 2-5% of the population older than 60 years and 10 percent of people older than 80 years.

Electrocardiogram: The electrocardiogram (ECG) is a diagnostic tool that measures and records the electrical activity of the heart

Feature Selection: *Feature selection* is a process frequently used in classification algorithm, wherein a subset of the features available from the data are selected for the classifier. The best subset contains the least number of dimensions or features that most contribute to a correct classification process.

Genetic Algorithm: Genetic Algorithms (GA) are a way of solving problems by mimicking the same processes mother nature uses. They use the same combination of selection, recombination and mutation to evolve a solution to a problem.

Genetic Programming: Genetic Programming (GP), evolved a solution in the form of a Lisp program using an evolutionary, population-based, search algorithm which extended the fixed-length concepts of genetic algorithms.

Soft-Computing: Refers to a collection of different paradigms (such as fuzzy logic, neural networks, simulated annealing, genetic algorithms and other computational techniques), which are focussed in analyze, model and discover information in very complex problems.

Support Vector Machine (SVM): Are a special Neural Networks that performs classification by constructing an N-dimensional hyperplane that separates the data into two categories.

Intelligent MAS in System Engineering and Robotics

INTRODUCTION

The concept of agent has been successfully used in a wide range of applications such as Robotics, e-commerce, agent-assisted user training, military transport or health-care. The origin of this concept can be located in 1977, when Carl Hewitt proposed the idea of an interactive object called *actor*. This actor was defined as a computational agent, which has a mail address and a behaviour (Hewitt, 1977). Actors receive messages from other actors and carry out their tasks in a concurrent way.

It is difficult that a single agent could be sufficient to carry out a relatively complex task. The usual approach consists of a society of agents - called Multiagent Systems (MAS) -, which communicate and collaborate among them and they are coordinated when pursuing a goal.

The purpose of this chapter is to analyze the aspects related to the application of MAS to System Engineering and Robotics, focusing on those approaches that combine MAS with other Artificial Intelligence (AI) techniques.

BACKGROUND

There is not an academic definition accepted by every researcher about the term agent. In fact, agent researchers have offered a variety of definitions explicating his or her particular use of the word. An extensive list of these definitions can be found in (Franklin and Graesser, 1996). It does not fall in the scope of this chapter to reproduce that list. However, we will include some of them, in order to illustrate how heterogeneous these definitions are.

“Autonomous agents are computational systems that inhabit some complex dynamic environment, sense and act autonomously in this environment, and by doing so realize a set of goals or tasks for which they are designed.” (Maes, 1995, p. 108)

“Autonomous agents are systems capable of autonomous, purposeful action in the real world.” (Brustoloni, 1991, p. 265)

“An agent is anything that can be viewed as perceiving its environment through sensors and acting upon that environment through effectors.” (Russell and Norvig, 1995, p. 31)

Despite the existing plethora of definitions, agents are often characterized by only describing their features (long-live, autonomy, reactivity, proactivity, collaboration, ability to perform in a dynamic and unpredictable environment, etc.). With these characteristics, users can delegate to agents tasks designed to be carried out without human intervention, for instance, as personal assistants that learn from its user.

In most of applications, a standalone agent is not sufficient for carrying out the desired task: agents are forced to interact with other agents, forming a MAS. Due to their capacity of flexible autonomous action, MAS can treat with open – or at least highly dynamic or uncertain- environments. On the other hand, MAS can effectively manage situations where distributed systems are needed: the problem being solved is itself distributed, the data are geographically distributed, systems with many components and huge content, systems with future extensions, etc. A researcher could include a single agent to implement all the tasks. Nevertheless, this type of macroagent represents a bottleneck for the system speed, reliability and management.

It is clear that the design of a MAS is more complex than a single agent. Apart from the code for the treatment of the task-problem, a developer needs to implement those aspects related to communication, negotiation among the agents and its organization in the system. Nevertheless, it has been shown that MAS offer more than they cost (Cockburn, 1996) (Gonzalez, 2006) (Gonzalez, 2006b) (Gyurjyan, 2003) (Seilonen 2005).

MAS, AI AND SYSTEM ENGINEERING

An important topic in System Engineering is that of process control problem. We can define it as the one of manipulating the input variables of a dynamic system in an attempt to influence over the output variables in a desired fashion, for example, to achieve certain values or certain rates (Jacquot, 1981). In this context, as other Engineering disciplines, we can find a lot of relevant formalisms and standards, whose descriptions are out of the scope of this chapter. An interested reader can get an introductory presentation of these aspects in (Jacquot, 1981).

Despite their advantages, there are few approaches to the application of MAS technology to process automation (much less than applications to other fields such as manufacturing industry). Some reasons for this lack of application can be found in (Seilonen, 2005):

- Process automation requires run-time specifications that are difficult to reach by the current agent technology.
- The parameters in the automation process design are usually interconnected in a strict way, thus it is highly difficult to decompose the task into agent behaviors.
- Lack of parallelism to be modeled through agents.

In spite of these difficulties, some significant approaches to the application of MAS to process control can be distinguished:

- An interesting approach of application of MAS to process control is that in which communication techniques among agents are used as a mechanism of integration among systems independently designed. An example of this approach is the

ARCHON (*Architecture for Cooperative Heterogeneous on-line systems*) architecture (Cockburn, 1996) that has been used in at least three engineering domains: Electricity Transportation, Electricity Distribution and Particle Accelerator Control. In ARCHON, each application program (known as *Intelligent System*) is provided with a layer (called *Archon Layer*) that allows it to transfer data/messages to other Intelligent Systems.

- A second approach consists of those systems that implement a closed loop-based control. In this sense, we will cite the work of (Velasco et al., 1996) for the control of a thermal central.
- A different proposal consists of complementing a pre-existing process automation system with agent technology. In other words, it is a complementation, not a replacement. The agent system is an additional layer that supervises the automation system and reconfigures it when it is necessary. Seilonen et al. also propose a specification of a BDI-model-based agent platform for process automation (Seilonen, 2005).
- V. Gyurjyan et al. (2003) propose a controller system architecture with the ability of combining heterogeneous processes and/or control systems in a homogeneous environment. This architecture (based on the FIPA standard) develops the agents as a level of abstraction and uses a description of the control system in a language called COOL (*Control Oriented Ontology Language*).
- Tetiker et al. (2006) propose a decentralized multi-layered agent structure for the control of distributed reactor networks where local control agents individually decide on their own objectives allowing the framework to achieve multiple local objectives concurrently at different parts of the network. On top of that layer, a global observer agent continuously monitors the system.
- Horling, Lesser et al. (2006) describe a soft real-time control architecture designed to address temporal and ordering constraints, shared resources and the lack of a complete and consistent world view. From challenges encountered in a real-time distributed sensor allocation environment, the system is able to generate schedules respecting temporal, structural and resource constraints, to merge new goals with existing ones, and to detect and handle unexpected results from activities. Other proposal of real-time control architecture

is CIRCA (*A Cooperative Intelligent Real-Time Control Architecture*) by Musliner, Durfee and Shin (1993), that uses separate AI and real-time subsystems to address the problems for which each is designed.

In this context, we proposed a MAS (called MAS-CONTROL) for identification and control of processes, whose design follows the FIPA specifications (FIPA, 2007) regarding architecture, communication and protocols. This MAS implements a self-tuning regulator (STR) scheme, so this is not a new general control algorithm but a new approach for its development. Its main contribution consists of showing the potential that a controller, through the use of MAS and ontologies – expressed in OWL (*Ontology Web Language*)–, can control systems in an autonomous way, using actions whose description, for example, is on the web, and can read on it (without knowing a priori) the logic of how to do the control. In this context, our experience is that agents do not offer any advantage if they are not intelligent and ontologies represent an intelligent way to manage knowledge since they provides the common format in which they can express that knowledge. Two important advantages of their use are extensibility and communication with other agents sharing the same language. These advantages are shown in the particular case of open systems, that is, when different MAS from different developers interact (Gonzalez, 2006).

As a STR, our MAS tries to carry out the processes of identification and control of a plant. We consider that this model can be properly managed by a MAS due to two main reasons:

- A STR scheme contains modules that are conceptually different, such as the direct interaction with the plant to control, identification of the system and determination of the best values for the controller parameters.
- It is possible to carry out the calculations in a parallel way. For instance, several transfer functions could be explored simultaneously. Thus, several agents can be launched in different computers, taking advantage of the possibility of parallelism provided by the MAS.

Other innovator aspect of this work is the use of artificial neural networks (ANN) for the identification and determination of the parameters. ANN and STR

present clear analogies. The training of a neural network consists of finding the best values of the weights of the network while it is necessary to optimize some parameters for a model (identification) or for a controller in a STR. Because of this similarity of methods, we have considered the application of ANN training methods to control problems. In this case, ANN are applied for two purposes: the parameter optimization of a model of the unknown system and the optimization of the parameters of a controller. This way, the resulting system could be seen as a hybrid intelligent system for a real-time application. An interested reader can get a deeper description of the system in (Gonzalez, 2006b).

It is important to remark that this framework can be used for every algorithm of identification and control. In this context, we have checked the MAS controlling several and different plants, obtaining a proper behavior. In contrast, due to the transmission rate and optimization time, the designed MAS should be used for the controlling of not-excessively fast processes, according to the first restriction stated above. However, we expect to have shown an example of how the other two (strong interdependency of the parameters and lack of parallelism) can be overcome.

As can be seen, the mentioned restrictions often become serious obstacles in the application of MAS to Engineering Systems. In this framework, the use of Fuzzy rules is a very usual solution in order to define single-agents behaviours (Hoffmann, 2003). Unfortunately, the definition of the rules is cumbersome in most cases. As a possible solution to the difficult task of generating the adequate rules, several automatic algorithms have been proposed. New rule extraction approaches based on connectionist models have been proposed. Among them, the Neuro-Fuzzy systems has been proven as a way to obtain the rules, taking advantage of the learning properties of the Neural Networks and the form of expressing the knowledge by Fuzzy rules (Mitra and Hayashi, 2000).

In this context, several applications have been developed. In Robotics applications, it could be cited the work of (Lee and Qian, 1998), who describe a two-component system for picking up moving objects for a vibratory feeder or the work of (Kiguchi, 2004), proposing a hierarchical neuro-fuzzy controller for a robotic exoskeleton, to assist motion of physically weak persons such as elderly, disabled, and injured persons. As a particular case, a system for the detection and identification of road markings will be presented

in this chapter. This system has been incorporated to a vehicle as it can be seen in Figure 1.

This system is based on infrared technology and a classification tool based on a Neuro-Fuzzy System. A particular feature to take into account in this kind of tasks is that the detection and classification have to be done in real time. Hence, the time consumed by the hardware system and the processing algorithms is critical in order to take a right decision within the time frame of its relevance. Looking for an inexpensive and fast system, the infrared technology is a good alternative solution in this kind of applications. In this direction, taking into account the time limitations, a combination between a device based on infrared technology and different techniques to extract convenient Fuzzy rules are used (Marichal, 2006). It is important to remark that the extraction and the interpretation of

the rules have generated great interest in recent years (Guillaume, 2007).

The final purpose is to achieve a MAS, where each agent does its work as fast as possible, overcoming the temporal limitations of the MAS as pointed out by (Seilonen, 2005). In this context, we would like to remark some approaches of MAS applied to decision fusion for distributed sensor systems, in particular that by Yu and Sycara (2006). In order to achieve the mentioned MAS, it is necessary to obtain the rules for each agent. Furthermore, a depth analysis over the rules has to be done, minimizing the number of them and setting the mapping between these rules and the different scenarios.

The approach used in the shown case is based on designing rules for each situation found by the vehicle. In fact, each different scenario should be expressed

Figure 1. Infrared system under the vehicle

Table 1. Rules extracted by the neuro-fuzzy approach

| | Arrow | Right Arrow | Yield | Forward- right Arrow | Other Rules |
|----------------------------|-------|----------------------|---------------------------|-------------------------------|-------------------|
| Range | [0 2) | [2 4) | [4 6) | [6 8] | [-1 0] |
| Reference Value | 1 | 3 | 5 | 7 | |
| Rules | 6, 7 | 8,9, 10,11, 12 | 13,14, 15,16, 17,18 | 19,20,21, 22,23, 24, 25 | 1,2, 3,4, 5 |

by its own rules. This feature gives more flexibility in the process of designing the desired MAS. Because of that, the separation of rules according to the kind of road marking could help in this purpose. In Table 1, it is shown the result of this process for the infrared system shown in Figure 1. Note that, the reference values are the values associated with each road marking, the range refers to the interval where the output values of the resultant Fuzzy system could be for a particular sign and finally, the rules are indicated by an order number.

It is important to remark that it is necessary to interpret the obtained rules. In this way, it is possible to associate these rules with different situations and generate new rules more appropriate for a particular case under consideration. Hence, the agents related with the detection and classification of the signs could be expressed by this set of Fuzzy rules. Moreover, agents, which are in charge of taking decisions based on the information, provided by the detection and classification of a particular road marking, could incorporate these rules as part of them. Problems in task decomposition process, pointed out by (Seilonen, 2005), could be simplified in this way. On the other hand, although the design of behaviors is very important, it should be said that the issues related with the co-operation among agents are also essential. In this context, the work of (Howard et al, 2007) could be cited.

FUTURE TRENDS

As technology provides faster and more efficient computers, the application of AI techniques to MAS is supposed to become increasingly popular. That improvement in the computer capacity and some emerging techniques (meta-level accounting, schedule caching, variable time granularities, etc.) (Horling, Lesser et al., 2006) will imply that other AI methods- impossible to be currently applied in the field of System Engineering- will be introduced in an efficient way in a near future.

In our opinion, other important feature to be explored is the improvement in MAS communication. It is also convenient to look for more efficient MAS protocols and standards, in addition to those aspects related to new hardware features. These improvements would allow, for example, developing operative real-time tele-operated applications.

CONCLUSION

The application of MAS to Engineering Systems and Robotics is an attractive platform for the convergence of various AI technologies. This chapter shows in a summarized manner how different AI techniques (ANN, Fuzzy rules, Neuro-Fuzzy systems) have been

successfully included into MAS technology in the field of System Engineering and Robotics. These techniques can also overcome some of the traditionally described drawbacks for MAS application, in particular, highly difficult decomposition of the task into agent behaviors and lack of parallelism to be modeled through agents.

However, present-day MAS technology does not fulfill completely the severe real-time requirements that are implicit in automation processes. Thus, and until the technology provides faster and more efficient computers, our opinion is that the application of AI techniques in MAS needs to be optimized for real-time systems, for example, extracting convenient Fuzzy rules and minimizing its number.

KEY TERMS

Artificial Neural Network: An organized set of many simple processors called *neurons* that imitates a biological neural configuration.

FIPA: It stands for “Foundation for Intelligent Physical Agents”, IEEE Computer Society standards organization that promotes agent-based technology and the interoperability of its standards with other technologies

MultiAgent System: System composed of several agents, usually designed to cooperate in order to reach a goal.

Neuro-Fuzzy: Hybrids of Artificial neural networks and Fuzzy Logic.

Ontology: Set of classes, relations, functions, etc. that represents knowledge of a particular domain.

Real-Time System: System with operational deadlines from event to system response.

Self-Tuning Regulator: Type of adaptive control system composed of two loops, an inner loop (process and ordinary linear feedback regulator), and an outer loop (recursive parameter estimator and design calculation which adjusts its parameters).

Intelligent Query Answering Mechanism in Multi Agent Systems

Safiye Turgay

Abant İzzet Baysal University, Turkey

Fahrettin Yaman

Abant İzzet Baysal University, Turkey

INTRODUCTION

The query answering system realizes the selection of the data, preparation, pattern discovering, and pattern development processes in an agent-based structure within the multi agent system, and it is designed to ensure communication between agents and an effective operation of agents within the multi agent system. The system is suggested in a way to process and evaluate fuzzy incomplete information by the use of fuzzy SQL query method. The modelled system gains the intelligent feature, thanks to the fuzzy approach and makes predictions about the future with the learning processing approach.

The operation mechanism of the system is a process in which the agents within the multi agent system filter and evaluate both the knowledge in databases and the knowledge received externally by the agents, considering certain criteria. The system uses two types of knowledge. The first one is the data existing in agent databases within the system and the latter is the data agents received from the outer world and not included in the evaluation criteria. Upon receiving data from the outer world, the agent primarily evaluates it in knowledgebase, and then evaluates it to be used in rule base and finally employs a certain evaluation process to rule bases in order to store the knowledge in task base. Meanwhile, the agent also completes the learning process.

This paper presents an intelligent query answering mechanism, a process in which the agents within the multi-agent system filter and evaluate both the knowledge in databases and the knowledge received externally by the agents. The following sections include some necessary literature review and the query answering approach. Then follow the future trends and the conclusion.

BACKGROUND

The query answering system in agents utilizes fuzzy SQL queries from the agents, then creates and optimizes a query plan that involves the multiple data source of the whole multi agent system. Accordingly, it controls the execution of the task to generate the data set. The query operation constitutes the basic function of query answering. By query operation, the most important function of the system is fulfilled. This study also discusses peer to peer network structure and SQL structure, as well as query operation.

Query operation was applied in various fields. For example, selecting the related knowledge in a web environment was evaluated in terms of relational concept in databases. Relational database system particularly assists the system in making evaluations for making decisions about the future and in making the right decisions with fuzzy logic approach (Raschia & Mauaddib, 2002; Tatarinov et al. 2003; Galindo et al. 2001; Bosc et al. Chaudhry et.al. 1999; Saygin et al. 1999; Turgay et al.2006).

Query operation was mostly used in choosing the related information web environment (Jim & Suciu, 2001; He et al. (2004). Data mining approach was used in dynamic site discovery process by the data preparation and type recognition approaches in complex matching schema with correlation values in query interfaces and query schemas (Nambiar & Kambhampati, 2006; Necib & Freytag, 2005). Query processing within peer to peer network structure with SQL structure was discussed generally (Cybenko et al. 2004; Bernstein et al. 1981). Query processing and database was reviewed with relational database (Genet & Hinze, 2004; Halashek-Wiener et al., 2006). Fuzzy set was proposed by Zadeh (1965) and the division of the features into various linguistic values was widely

used in pattern recognition and in the fuzzy inference system. Kubat, et al. (2004) reviewed the frequency of the fuzzy logic approach in operations research methods as well as artificial intelligence ones in discrete manufacturing. Data processing process within the multi-agent systems can be grouped as static and dynamic. While the evaluation process of existing data by the system can be referred to as a static structure, the evaluation process of new data or possible data within the system can be referred to as a dynamic structure. The studies on the static structure can be expressed as database management's query process (McClean, Scotney, Rutjes & Hartkamp, 2003) and the studies on the dynamic structure can be expressed as the whole of the agent system (Purvia, Cranefield, Bush & Carter, 2000; Hoschek, 2002; Doherty, Lukaszewicz, & Szalas, 2004, Turgay, 2006)

AGENT BASED QUERY ANSWERING SYSTEM

The query process lists the knowledge with desired characteristics in compliance with the required condition while query answering finds the knowledge conforming to the required conditions and responds to the related message in the form of knowledge. In par-

ticular, a well-defined query answering process within multi agent systems provides communication among agents, the sharing of knowledge and the effective performance of data processing process and learning activities. The system is able to process incomplete or fuzzy knowledge intelligently with the fuzzy SQL query approach.

The distributed query answering mechanism was proposed as a cooperative agent-based solution for information management with fuzzy SQL query. A multi-agent approach to information management includes some features such as:

- Concurrency
- Distributed computation
- Modularity
- Cooperation

Figure 1 represents each agent's query answering mechanism. When the data is received by the system, the query variables are chosen by query and then the data related with fuzzy SQL are suggested. The obtained result is represented as the answer knowledge in the agent and thus the process is completed.

The data are classified by the fuzzy query approach, depending on fuzzy relations and importance levels. The rule base of the system is formed after a

Figure 1. Model driven framework for query answering mechanism in a multi-agent system

query and evaluation. The task base structure of the system is updated by the mechanism in line with the obtained fuzzy rules, and then, it is ensured that the system makes an appropriate and right decision and acts intelligently.

Operation Mechanism of Agent Based Fuzzy Query Answering System

The agent does the following:

- Step1: receives the task knowledge from the related agent
- Step2: does the fuzzification of knowledge
- Step3: determines fuzzy grade values according to knowledge features

Step4: determines the knowledge in compliance with the criteria through fuzzy SQL commands

Step5: sends the obtained task or rule to the related agent

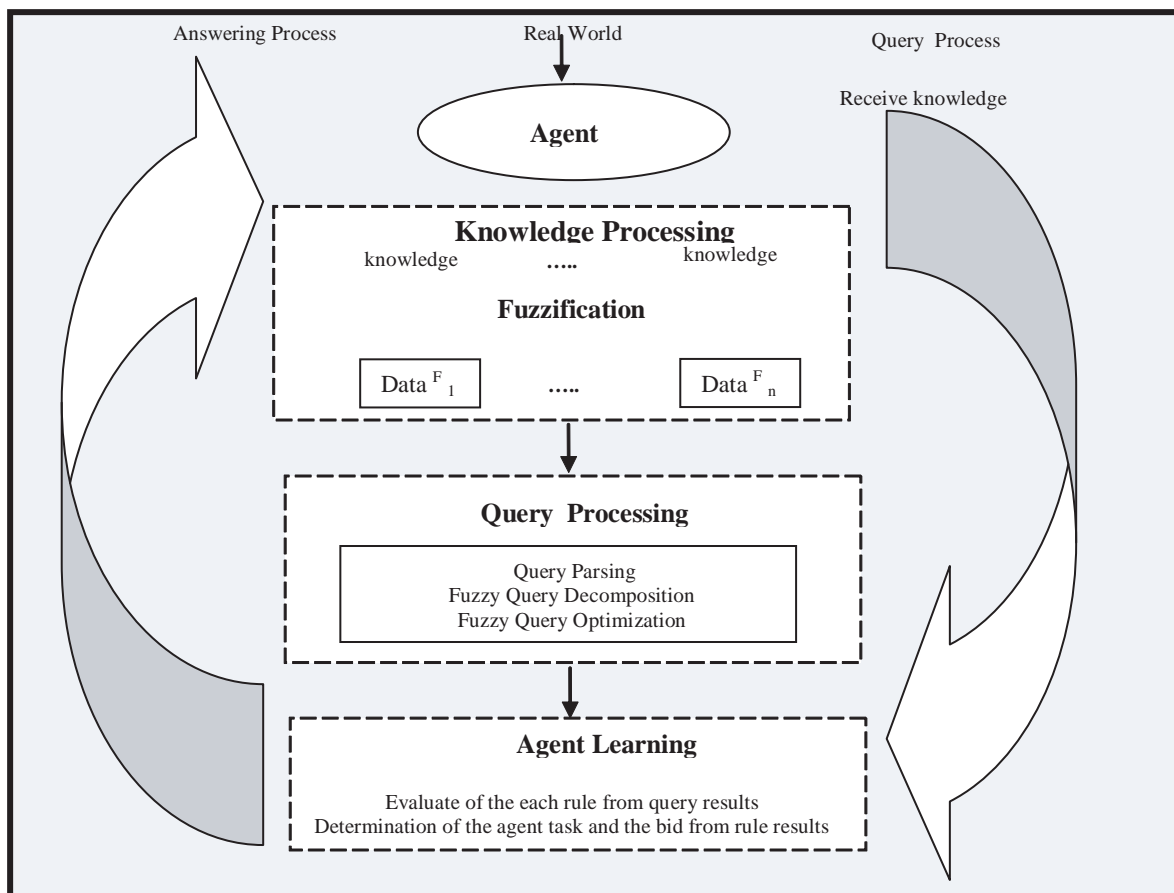

Step6: performs the answering operation

The agent based query answering system involves three main stages: knowledge processing, query processing and agent learning (see Figure2). The operation types of these stages are given in detail below.

Knowledge Processing

This is the stage where the knowledge is received by the agent from the external environment and necessary preparations are made before query. The criteria and

Figure 2. Suggested system model for each agent

keywords to be used in evaluating the received data are defined in this stage. This stage can also be called pre-query. The keywords, concepts, attribute and relationship knowledge to be analysed by the agent are determined in this stage before query.

In this system, the behaviour structure of intelligent query answering system is formed. During the system modelling, the perception model considered being coming signal, data and knowledge from the external environment for a more understandable structure in learning module plays an important role. Coming from the external environment and called the input modelling; $\langle A_{i,x}, A_i, \emptyset \rangle$ is defined as the perception set. Agent i , x perception coming from the external environment, refer to the $A_{i,x}$. Table 1 includes the nomenclature of agent based query answering system. The multi-agent system consists of more than one agent. The agent set is $A = \{A_1, A_2, \dots, A_i\}$. The knowledge set is $K = \{K_1, K_2, \dots, K_y\}$. The knowledgebase is $\langle \text{Definition of Knowledge, Attribute, Dependency Situation, Agent} \rangle$ (in Table 1 and Figure 3).

The rule set is $R = \{R_1, R_2, \dots, R_x\}$. The rule base is $\langle \text{Definition of Rule, Attribute, Dependency Situation, Agent} \rangle$. The task set is $T = \{T_1, T_2, \dots, T_j\}$. The task base is $\langle \text{Definition of Task, Attribute, Dependency Situation, Agent} \rangle$.

When data arrives from the external environment, it is perceived as input : $\langle A_{i,x}, A_i, \emptyset \rangle$ When “x” is

perceived by Agent i , it is referred to as $A_{i,x}$. This input can also be used in knowledgebase, rule base and task base. **The following goals that were determined as a result of the process and the evaluation of the information coming to the knowledge-base should have been achieved in the mechanism of intelligent query answering.**

- Goal definition
- Data selection
- Data preparation

Query Processing

The agent performs two types of query in the process of defining keywords, concepts or attributes during knowledge processing. The first is external query, which is realized among the agents, while the second is the internal query, where the agent scans the knowledge within itself. During these query processes, the fuzzy SQL approach is applied.

Feature-Attribute At and relation Re are elements formed among the components within the system. These elements are the databases of knowledgebase, rule base and task base. While attribute refers to agent specifications, Resource includes not only raw data externally received but also knowledgebase, rule base and task base which each agent possesses.

Table 1. The nomenclature of agent based query answering system

| | |
|--------------------------|--|
| A | $\rightarrow i$ agent set $\{A_1, A_2, \dots, A_i\}$ |
| T | $\rightarrow j$ task set in $\{T_1, T_2, \dots, T_j\}$ |
| $A_{i,x}$ | $\rightarrow i$ agents x percept |
| $\bigcup_{k=1}^m T_{jk}$ | $\rightarrow i$ agent's j task sets refers to continuing subsets from k to m situation |
| $L_{i,m}$ | $\rightarrow i$ agents m learning situation |
| $Q_{i,n}$ | $\rightarrow i$ agents n querying situation |
| At_i | $\rightarrow i$ agents attribute situation |
| $R_{i,r}$ | $\rightarrow i$ agent's r decision situation |
| $K_{i,y}$ | $\rightarrow i$ agent's y knowledgebase |
| $R_{i,x}$ | $\rightarrow i$ agent's x rule base |
| $T_{i,t}$ | $\rightarrow i$ agent's t task base |

$$A = \{At, Re(K_{i,y}, R_{i,x}, T_{i,t})\}$$

Let $P(At)$ denote the set of all possibility distributions that may be defined over the domain of an attribute At . A fuzzy relation R with \cup schema A_1, A_2, \dots, A_n , where A_i is an attribute is defined as $R = P(At_1) \times P(At_2) \times \dots \times P(At_n) \times D$, where D is a system-supplied attribute for membership degree with a domain $[0,1]$ and \times denotes the cross product.

Each data value V of the attribute is associated with a possibility distribution defined over the domain of the attribute and has a membership function denoted by $\mu_v(x)$. If the data value is crisp, its possibility distribution is defined by

$$\mu_v(x) = \begin{cases} 1 & \text{if } x = v \\ 0 & \text{otherwise} \end{cases} \quad (1)$$

Like standard SQL, queries in fuzzy SQL are specified in select statement of the following form:

| | |
|--------|-----------------------|
| SELECT | Attributes |
| FROM | Relations |
| WHERE | Selection Conditions. |

The semantics of a fuzzy SQL query is defined based on satisfaction degrees of query conditions. Consider a predicate $X\Theta Y$ in a WHERE clause. The satisfaction degree, denoted by $d(X\Theta Y)$, is evaluated for values of X and Y . Let the value of X be v_1 and that of Y of v_2 . Then,

$$d(X\Theta Y) = \max_{X,Y} (\min(\mu_{v_1}(X), \mu_{v_2}(Y), \mu_{\Theta})) \quad (2)$$

where X and Y are crisp values in the common domain over which v_1 and v_2 are defined (Yang et al., 2001). Function Θ is a function that compares the degrees in terms of satisfaction among the variables. When the satisfaction degree is evaluated for X and Y the former takes the value of v_1 , while the latter takes the value of v_2 .

As shown in Figure 2, bids are taken as a set, the frequencies of the received bids are fixed and then the bids are decomposed into groups. The decomposed

bids are included into databases of the multi-agent system. The information in databases is fuzzified and the interrelation between them is determined in terms of weight and importance level.

Agent Learning Process

This is a process where the system learns the knowledge obtained as a result of query as a rule or task. The system fulfils not only the task but also the learning process (in Figure 3). Learning process is acquired and the data from the external transition is processed by the agent system of the defined aim during the activities. Learning algorithm shows the variability of the system status (in Table 2).

In the learning process with the help of the query processing, candidate rules are determined by taking the fuzzy dimension attributes and the attribute measures into consideration. Therefore, it would be true to say that a hierarchical order from knowledge-base to rule-base and from rule-base to task-base is available in the system.

Algorithm Learning Analysis

Input: A relational view that contains a set of records and the questions for influence analysis.

Output: An efficient association rule.

Step1: Specifies the fuzzy dimension attribute and the measure attribute.

Step2: Identifies the fuzzy dimension item sets and calculates the support coefficient

Step3: Identifies the measure item sets and calculates the support coefficient.

Step4: Constructs sets of candidate rules, and computes the confidence and aggregate value.

Step5: Obtains a rule at the granularity level with greatest confidence, and forms a rule at the aggregation level with largest abstract value of the measure attribute.

Step6: Computes the assertions at different levels, exits if comparable (i.e., there is no inconsistency found in semantics at different levels).

Step7: Generates rules from the refined measure item sets and forms the framework of the rule.

Step8: Constructs the final rule as a task for related agent.

Table 2. The query answering mechanism's learning analysis algorithm

Figure 3. The way the input perceived by the agent is processed

FUTURE TRENDS

Future tasks of the system will be realized when the system performs query answering more quickly thanks to the distributed, autonomous, intelligent and communicative agent structure of the suggested agent based fuzzy query answering system. In fuzzy approach, the system will primarily examine and group the relational database in databases of the agents with the fuzzy logic and then will shape the rule base of the system by applying the fuzzy logic method to these data. After the related rule is chosen, the rule base of the system will be designed and the decision mechanism of the system will operate. Therefore, relational database structure and system behaviour are important in determining the first peculiarity of the system and in terms of data clearing.

For future research, it is noted that the design of fuzzy databases involves not just modelling the data but also modelling operations on the data. Relational databases support only limited data types, while fuzzy and possibility databases allow a much larger number of comparatively complex data types (e.g., possibility distributions). This suggests that it might be fruitful to employ object-oriented database technology to allow explicit modelling of complex data types.

The incorporation of fuzziness into distributed events can be performed as a future study. Finally, due to frequent changes in the positions and status of objects in an active mobile database environment, the issue of temporality should be considered by adapting the research results of temporal database systems area into active mobile databases.

CONCLUSION

This paper discusses a variety of issues in adapting fuzzy database concepts to an active multi agent database system which incorporates active rules in a multi computing environment. This study shows how fuzziness can be introduced to different aspects of rule execution from event detection to coupling modes. As an initial step, membership degree calculation for various types of composite events has been explained. Dynamic determination of coupling modes has been done by using the strengths of events and reliabilities of conditions which are calculated via membership functions. Strengths of events and condition reliabili-

ties have been shown to be useful for condition and action status, as well. The partitioning of the rule set into multi agent system events has also been discussed as an example of inter-rule fuzziness. Similarity based event detection has been introduced to active multi agent databases, which is an important contribution from the perspective of performance.

KEY TERMS

Agent : A system that fulfils the independent functions, perceives the outer world and establishes the linking among the agents through its software.

Flexible Query: Incorporates some elements of the natural language so as to make a possible simple and powerful expression of subjective information needs.

Fuzzy SQL (Structural Query Language): It is an extension of the SQL language that allows us to write flexible conditions in our queries. The FSQL allows us to use linguistic labels defined on any attribute.

Fuzzy SQL Query: Fuzzy SQL allows the system to make flexible queries about crisp or fuzzy attributes in fuzzy relational data or knowledge.

Intelligent Agent: It consists of a sophisticated intelligent computer program; which is acting of situated, independent, reactive, proactive, flexible, recovers from failure and interacts with other agents.

Multi-Agent System: It is a flexible incorporated network of software agents that interact to solve the

problems that are beyond the individual capacities or knowledge of each problem solver.

Query: Caries out the scanning of the data with required specifications.

Query Answering: Answers a user query with the help of a single or multi-database in the multi agent system.

System: A set of components considered to act as a single goal-oriented entity.

INTRODUCTION

The **Artificial Neural Networks (ANNs)** are based on the behaviour of the brain. So, they can be considered as **intelligent systems**. In this way, the ANNs are constructed according to a brain, including its main part: the neurons. Moreover, they are connected in order to interact each other to acquire the followed intelligence. And finally, as any brain, it needs having memory, which is achieved in this model with their weights.

So, starting from this point of view of the ANNs, we can affirm that these systems are able to learn difficult tasks. In this article, the task to learn is to distinguish between the presence or not of a reflected signal called **target** in a Radar environment dominated by **clutter**. The **clutter** involves all the signals reflected from other objects in a Radar environment that are not the desired **target**. Moreover, the **noise** is considered in this environment because it always exists in all the communications systems we can work with.

BACKGROUND

The ANNs, as **intelligent systems**, are able to detect known **targets** in adverse Radar conditions. These conditions are related with one of the most difficult **clutter** we can find, the coherent Weibull **clutter**. It is possible because ANNs trained in a supervised way can

approximate the Neyman-Pearson (NP) detector (De la Mata-Moya, 2005, Vicen-Bueno, 2006, Vicen-Bueno, 2007), which is usually used in Radar systems design. This detector maximizes the probability of detection (P_d) maintaining the probability of false alarm (P_{fa}) lower than or equal to a given value (VanTrees, 1997). The detection of **targets** in presence of **clutter** is the main problem in Radar detection systems. Many **clutter** models have been proposed in the literature (Cheikh, 2004), although one of the most used models is the Weibull one (Farina, 1987a, DiFranco, 1980).

The research shown in (Farina, 1987b) set the optimum detector for **target** and **clutter** with arbitrary Probability Density Functions (PDFs). Due to the impossibility to obtain analytical expressions for the optimum detector, only suboptimum solutions were proposed. The Target Sequence Known A Priori (TSKAP) detector is one of them and is taken as reference for the experiments. Also, these solutions convey implementation problems, some of which make them non-realizable.

As mentioned above, one kind of ANNs, the **MultiLayer Perceptron (MLP)**, is able to approximate the NP detector when it is trained in a supervised way to minimize the Mean Square Error (MSE) (Ruck, 1990, Jarabo, 2005). So, **MLPs** have been applied to the detection of known **targets** in different Radar environments (Gandhi, 1997, Andina, 1996).

INTELLIGENT RADAR DETECTORS BASED ON ARTIFICIAL NEURAL NETWORKS

This section starts with a discussion of the models selected for the **target**, **clutter** and **noise** signals. For these models, the optimum and suboptimum detectors are presented. These detectors will be taken as a reference for the experiments. After, it is presented the intelligent detector proposed in this work. This detector is based on **intelligent systems** like the ANNs, and a further analysis of its structure and parameters is made. Finally, several results are obtained for the detectors under study in order to analyze their performances.

Signal Models: Target, Clutter and Noise

The Radar is assumed to collect N pulses in a scan, so input vectors (z) are composed of N complex samples, which are presented to the detector. Under hypothesis H_0 (target absent), z is composed of N samples of **clutter** and **noise**. Under hypothesis H_1 (target present), a known **target** characterized by a fixed amplitude (A) and phase (θ) for each of the N pulses is summed up to the **clutter** and **noise** samples. Also, a Doppler frequency in the target model of $0,5 \cdot \text{PRF}$ is assumed, where PRF is the Pulse Repetition Frequency of the Radar system.

The **noise** is modelled as a coherent white Gaussian complex process of unity power, i.e., a power of $\frac{1}{2}$ for the quadrature and phase components, respectively. The **clutter** is modelled as a coherent correlated sequence with Gaussian AutoCorrelation Function (ACF), whose complex samples have a modulus with a Weibull PDF:

$$p(|w|) = ab^{-a} |w|^{a-1} e^{-\left(\frac{|w|}{b}\right)^a} \quad (1)$$

where $|w|$ is the modulus of the coherent Weibull sequence and a and b are the skewness (shape) and scale parameters of a Weibull distribution, respectively.

The $N \times N$ autocorrelation matrix of the clutter is given by

$$(M_c)_{h,k} = P_c \rho_c^{|h-k|} e^{j\left(2\pi(h-k)\frac{f_c}{\text{PRF}}\right)} \quad (2)$$

where the indexes h and k varies from 1 to N , P_c is the clutter power, ρ_c is the one-lag correlation coefficient and f_c is the Doppler frequency of the clutter.

The relationship between the Weibull distribution parameters and P_c is

$$P_c = \frac{2b^2}{a} \Gamma\left(\frac{2}{a}\right) \quad (3)$$

where $\Gamma(\cdot)$ is the *Gamma function*.

The model used to generate coherent correlated Weibull sequences consists of two blocks in cascade: a correlator filter and a NonLinear MemoryLess Transformation (NLMLT) (Farina, 1987a). To obtain the desired sequence, a coherent white Gaussian sequence is correlated with the filter designed according to (2) and (3). The NLMLT block, according to (1), gives the desired Weibull distribution to the sequence. So, in that way, it is possible to obtained a coherent sequence with the desired correlation and PDF.

Taking into consideration that the complex **noise** samples are of unity variance (power), the following power relationships are considered for the study:

- **Signal to Noise Ratio:** $\text{SNR} = 10\log_{10}(A^2)$
- **Clutter to Noise Ratio:** $\text{CNR} = 10\log_{10}(P_c)$

Neyman-Pearson Detectors: Optimum and Suboptimum Detectors

The problem of optimum Radar detection of **targets** in **clutter** is explored in (Farina, 1987a) when both are time correlated and have arbitrary PDFs. The optimum detector scheme is built around two non-linear estimators of the disturbances in both hypotheses, which minimize the MSE. The study of Gaussian correlated **targets** detection in Gaussian correlated **clutter** plus **noise** is carried out, but for the cases where the hypothesis are non-Gaussian distributed, only suboptimum solutions are studied.

The proposed detectors basically consist of two channels. The upper channel is matched to the conditions that the sequence to be detected is the sum of the **target** plus **clutter** in presence of **noise** (hypothesis H_1). While the lower one is matched to the detection of **clutter** in presence of **noise** (hypothesis H_0).

For the detection problem considered in this paper, the suboptimum detection scheme (TSKAP) shown in figure 1 is taken. Considering that the **CNR** is very

Figure 1. Target sequence known a priori detector

high ($\text{CNR} \gg 1$), the inverse of the NLMLT is assumed to transform the Weibull **clutter** in Gaussian, so the Linear Prediction Filter (LPF) is a N-1 order linear one. Then, the NLMLT transforms the filter output in a Weibull sequence. Besides being suboptimum, this scheme presents two important drawbacks:

1. The prediction filters have N-1 memory cells that must contain the suitable information to predict correct values for the N samples of each input pattern. So $N+(N-1)$ pulses are necessary to decide if the target is present or not.
2. The target sequence must be subtracted from the input of the H1 channel.

There is no sense in subtracting the **target** component before deciding if this component is present or not. So, in practical cases, it makes this scheme non-realizable.

Intelligent Radar Detectors

In order to overcome the drawbacks of the scheme proposed in the previous section, a detector based on a **MLP** with log-sigmoid activation function in its hidden and output neurons with hard limit threshold after its output is proposed. Also, as **MLPs** have been probed to approximate the NP detector when minimizing the MSE (Jarabo, 2005), it can be expected that the MLP-based detector outperforms the suboptimum scheme proposed in (Farina, 1987a).

MLPs have been trained to minimize the MSE using two algorithms: the back-propagation (BP) with vary-

ing learning rate and momentum (Haykin, 1999) and the Levenberg-Marquardt (LM) with varying adaptive parameter (Bishop, 1995). While BP is based on the steepest descent method, the LM is based on the Newton method, which is designed specifically for minimizing the MSE. For **MLPs** which have up to few hundred of weights (W), the LM algorithm is more efficient than the BP one with variable learning rate or the conjugate gradient algorithms, being able to converge in many cases when the other two algorithms fail (Hagan, 1994). The LM algorithm uses the information (estimation of the $W \times W$ Hessian matrix) of the error surface in each iteration to find the minimum. It makes this algorithm faster than the previous ones.

Cross-validation is used with both training algorithms, where training and validation sets are synthetically generated. Moreover, a new set (test set) of patterns is generated to test the trained **MLP** for estimating the Pfa and Pd using Montecarlo simulation. All the patterns of the three sets are generated under the same conditions (SNR, CNR and a parameters of the Radar problem) in order to study the capabilities of the **MLP** plus hard limit thresholding working as a detector.

MLPs are initialized using the Nguyen-Widrow method (Nguyen, 1999) and, in all cases, the training process is repeated ten times to guarantee that the performance of all the **MLPs** is similar in average. Once all the **MLPs** are trained, the best **MLP** in terms of the estimated MSE with the validation set is selected, in order to avoid the problem of keeping in local minima at the end of the training.

The architecture of the **MLP** considered for the experiments is I/H/O, where I is the number of **MLP**

inputs, H is the number of hidden neurons in its hidden layer and O is the number of **MLP** outputs. As the **MLPs** work with real arithmetic, if the input vector (z) is composed of N complex samples, the **MLP** will have $2N$ inputs (N in phase and N in quadrature components). The number of **MLP** independent elements (weights) to solve the problem is $W=(I+1) \cdot H+(H+1) \cdot O$, including the bias of each neuron.

Results

The performance of the detectors exposed in the previous sections is shown in terms of the Receiver Operating Characteristics (ROC) curves. They give the estimated P_d for a desired P_{fa} , which values are obtained varying the output threshold of the detector. The experiments presented are made for an integration of two pulses ($N=2$). So, in order to test correctly the TSKAP detector, observation vectors (also called patterns during the text) of length 3 ($N+(N-1)$) complex samples are generated, due to memory requirements of the TSKAP detector ($N-1$ pulses).

The a priori probabilities of H_0 and H_1 hypothesis are supposed to be the same. Three sets of patterns are generated for each experiment: train, validation and test sets. The first and the second ones have $5 \cdot 10^3$ patterns, respectively. The third one has $2.5 \cdot 10^6$ patterns, so the error in the estimation of the P_{fa} and the P_d is lower than 10% of the estimated values in the worst case ($P_{fa}=10^{-4}$). The patterns of all the sets are synthetically generated under the same conditions. These conditions involve typical values (Farina, 1987a, DiFranco, 1980, Farina, 1987b) for the **SNR** (20 dB), the **CNR** (30 dB) and the a ($a=1.2$) parameter of the Weibull-distributed **clutter**.

The **MLP** architecture used to generate the MLP-based detector is 6/ H /1. The number of **MLP** outputs ($O=1$) is established by the problem (binary detection). The number of hidden neurons (H) is studied in this work. And the number of **MLP** inputs ($I=6$) is established according to the next criterion. A total of 6 inputs ($2(N+(N-1))$) are selected when the MLP-based detector wants to be compared with the TSKAP detector in the same conditions, i.e., when both detectors have the same available information (3 pulses for an integration of $N=2$ pulses). Because of the TSKAP detector memory requirements, this case is considered.

Figure 2 shows the results of a study when 3 pulses are used to take the final decision by the MLP-based

detector according to the criterion exposed above. The study shows the influence of the training algorithm and the **MLP** size, i.e., the number of independent elements (W weights) that has the **ANN** to solve the problem. For the case of study, two important aspects have to be noted. The first one is related with the training algorithm. As can be observed, the performance achieved with a low size **MLP** (6/05/1) is very similar for both training algorithms (LM and BP). But when the **MLP** size is greater, for instance, 6/10/1, the performance achieved with the LM algorithm is better than the performance achieved with the BP one. It is due to the LM algorithm is more efficient than the BP one finding the minimum of the error surface. Moreover, the **MLP** training with LM is faster than the training with BP, because the number of training epochs can be reduced in an order of magnitude. The second aspect is related with the **MLP** size. As can be observed, no performance improvement is achieved when 20 or more hidden neurons are used comparing both algorithms as occurred with 10 hidden neurons. Moreover, from 20 ($W=121$ weights) to 30 ($W=181$ weights) hidden neurons, the performance tends to a maximum value (independently of the training algorithm used), i.e., almost no performance improvement is achieved with more weights. So, an MLP-based detector with 20 hidden neurons achieves an appropriate performance with low complexity.

A comparison between the performances achieved with the TSKAP detector and the MLP-based detector of size 6/20/1 trained with BP and LM algorithms is shown in figure 3. Two differences can be observed. The first one is that the MLP-based detector performance is practically independent of the training algorithm, comparing their results with the ones obtained for the TSKAP detector. And the second one is that the 6/20/1 MLP-based detector is always better than the TSKAP detector when they are compared in the same conditions of availability of information, i.e., with the availability of 3 ($N+(N-1)$) pulses to decide. Under these conditions and comparing figures 2 and 3, it can be observed that a 6/05/1 MLP-based detector is enough to overcome the TSKAP one.

The appreciated differences between the TSKAP and MLP-based detectors appear because the first one is a suboptimum detector and the second one approximates the optimum one, but it will be always worse than the optimum detector. It can not be demonstrated because an analytical expression for the optimum detector

Figure 2. MLP-based detector performances for different structure sizes (6/H/1) and different training algorithms: (a) BP and (b) LM

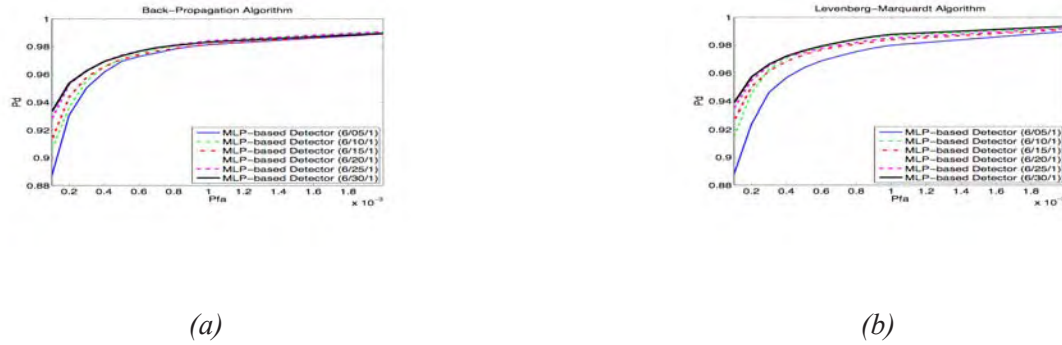

Figure 3. TSKAP and MLP-based detectors performances for MLP size 6/20/1 trained with BP and LM algorithms

can not be obtained detecting **targets** in presence of Weibull-distributed **clutter**.

FUTURE TRENDS

Two different future trends can be mentioned. The first one is related with **ANNs** and the second one is

related with the research in Radar detectors. In the first trend, it is possible to emphasize the research in areas like ensembles of **ANNs**, committee machines based on **ANNs** and others way to combine the intelligence of different **ANNs** like the **MLPs**, the Radial Basis Functions and others. Moreover, new trends try to find different ways to train **ANNs**. In the second trend, several researchers are trying to find different ways to create radar detectors in order to improve their performances. Moreover, several solutions are proposed, but they depend on the Radar environment considered. So, detectors based on signal processing tools seem to be the most appropriated, but the intelligent detector exposed here is a new way of working, which can brings good solutions to these problems. This is possible because of the intelligence of the **ANNs** to adapt to almost any kind of Radar conditions and problems.

CONCLUSION

After the developed study, several conclusions can be set. The LM training algorithm achieves better MLP-based detectors than the BP one. No performance improvement is obtained for training MLPs with LM or BP algorithms when their sizes are greater than 6/20/1. But, the great advantage of the LM one against the BP one is its fastest training for low size MLPs (a

few hundred of weights), i.e., the MLPs considered in this study. Finally, the MLP-based detector works better than the TSKAP one in cases of working with the same available information ($N+(N-1)=3$), because the memory requirements of the TSKAP one. In those cases, low complexity MLP-based detectors can be obtained because a 6/05/1 MLP has enough intelligence to obtain better performance than the TSKAP one.

KEY TERMS

Artificial Neural Networks (ANNs): A network of many simple processors (“units” or “neurons”) that imitates a biological neural network. The units are connected by unidirectional communication channels, which carry numeric data. Neural networks can be trained to find nonlinear relationships in data, and are used in applications such as robotics, speech recognition, signal processing or medical diagnosis.

Backpropagation Algorithm: Learning algorithm of ANNs, based on minimising the error obtained from the comparison between the ANN outputs after the application of a set of network inputs and the desired

outputs. The update of the weights is done according to the gradient of the error function evaluated in the point of the input space that indicates the input to the ANN.

Knowledge Extraction: Explication of the internal knowledge of a system or set of data in a way that is easily interpretable by the user.

Intelligence: It is a property of mind that encompasses many related abilities, such as the capacities to reason, plan, solve problems, think abstractly, comprehend ideas and language, and learn.

Levenberg-Marquardt Algorithm: Similar to the Backpropagation algorithm, but with the difference that the error is estimated according to the Hessian Matrix. This matrix gives information of several directions

where to go in order to find the minimum of the error function, instead of the local minimum one that gives the backpropagation algorithm.

Probability Density Function: The statistical function that shows how the density of possible observations in a population is distributed.

Radar: It is the acronym of Radio Detection and Ranging. In few words, a Radar emits an electromagnetic wave that is reflected by the target and others objects present in its observation space. Finally, the Radar receives these reflected waves (echoes) to analyze them in order to decide whether a target is present or not.

Intelligent Software Agents Analysis in E-Commerce I

Virginia State University, USA

INTRODUCTION

Equipped with sophisticated information technology infrastructures, the information world is becoming more expansive and widely interconnected. Internet usage is expanding throughout the web-linked globe, which stimulates people's need for desired information in a timely and convenient manner. Electronic commerce activities, powered by Internet growth, are increasing continuously. It is estimated that online retail will reach nearly \$230 billion and account for 10% of total U.S. retail sales by 2008 (Johnson et al. 2003). In addition, e-commerce entailing business-to-business (B2B), business-to-customer (B2C) and customer-to-customer (C2C) transactions is spawning new markets such as mobile commerce.

By increasing the degree and sophistication of the automation, commerce becomes much more dynamic, personalized, and context sensitive for both buyers and sellers. Software agents were first used several years ago to filter information, match people with similar interests, and automate repetitive behavior (Maes et al. 1999). In recent years, agents have been applied to the arena of e-commerce, triggering a revolutionary change in the way we conduct online transactions in B2B, B2C, and C2C. Researchers argue that the potential of the Internet for transforming commerce is largely unrealized (Begin et al. 2002; Maes et al. 1999). Further, He and Jennings noted that a new model of software agent is needed to achieve the degree of automation and move to second generation e-commerce applications (He et al. 2003). This is due to the predicament that electronic purchases are still largely unautomated. Maes et al. (1999) also addressed that, even though information is more easily accessible and orders and payments are dealt with electronically, humans are still in the loop in all stages of the buying process, which inevitably increase the transaction costs. Undoubtedly,

a human buyer is still responsible for collecting and interpreting information on merchants and products, making decisions about merchants and products, and ultimately entering purchase and payment information. Additionally, Jennings et al. (1998) confirmed that commerce is almost entirely driven by human interactions and further argued that there is no reason why some commerce cannot be automated.

This unautomated loop requires a lot of time and energy and results in inefficiency and high cost for both buyers and sellers. To automate time-consuming tasks, intelligent software agent (ISA) technology can play an important role in online transaction and negotiation due to its capability of delivering unprecedented levels of autonomy, customization, and general sophistication in the way e-commerce is conducted (Sierra et al. 2003). Systems containing ISAs have been developed to automate the complex process of negotiating a deal between a buyer and a seller. An increasing number of e-commerce agent systems are being developed to support online transactions that have a number of variables to consider and to aim for a win-win result for sellers and buyers.

In today's e-commerce arena, systems equipped with ISAs may allow buyers and sellers to find the best deal taking into account the relative importance of each factor. Advanced systems of e-commerce that embody ISA technologies are able to perform a number of queries and to process phenomenal volumes of information. ISAs reduce transaction costs by collecting information about services and commodities from a lot of firms and presenting only those results with high relevance to the user. ISA technologies help businesses automate information transaction activity, largely eliminate human intervention in negotiation, lower transaction and information search cost, and further cultivate competitive advantage for companies. Therefore, ISAs can free people to concentrate on the

issues requiring true human intelligence and intervention. Implementing the personalized, social, continuously running, and semi-autonomous ISA technologies in business information systems, the online business can become more user-friendly, semi-intelligent, and human-like (Pivk 2003).

LITERATURE REVIEW

A number of scholars have defined the term *intelligent software agent*. Bradshaw (1997) proposed that one person's intelligent agent is another person's smart object. Jennings and Wooldridge (1995) defined agents as a computer system situated in some environment that is capable of autonomous action in this environment to meet its design objective. Shoham (1997) further described an ISA as a software entity which functions continuously and autonomously in a particular environment, often inhabited by other agents and processes. In general, an ISA is *a software agent that uses Artificial Intelligence (AI) in the pursuit of the goals of its clients* (Croft 2002). It can perform tasks independently on behalf of a user in a network and help users with information overload. It is different from current programs in terms of being proactive, adaptive, and personalized (Guttman et al. 1998b). Also, it can actively initiate actions for its users according to the configurations set by the users; it can read and understand user's preferences and habits to better cater to user's needs; it can provide the users with relevant information according to the pattern it adapts from the users.

ISA is a cutting-edge technology in computational sciences and holds considerable potential to develop new avenues in information and communication technology (Shih et al. 2003). It is used to perform multi-task operations in decentralized information systems, such as the Internet, to conduct complicated and wide-scale search and retrieval activities, and assist in shopping decision-making and product information search (Cowan et al. 2002). ISA's ability of performing continuously and autonomously stems from human desire in that an agent is capable of operating certain activities in a flexible and intelligent manner responsive to changes in the environment without constant human supervision. Over a long period of time, an agent is capable of adapting from its previous experience and would be able to inhabit an environment with other

agents to communicate and cooperate with them to achieve tasks for human.

Intelligent Agent Taxonomy and Typology

Franklin and Grasser (1996) proposed a general taxonomy of agent (see Figure 1).

This taxonomy is based on the fact that ISA technologies are implemented in a variety of areas, including biotechnology, economic simulation and data-mining, as well as in hostile applications (malicious codes), machine learning and cryptography algorithms. In addition, Nwana (1996b) proposed the agent typology (see Figure 2) in which four types of agents can be categorized: collaborative agents, collaborative learning agents, interface agents and smart agents. These four agents have different congruence amid learning, autonomy, and cooperation and therefore tend to address different sides of this topology in terms of the functionality.

According to Nwana (1996b), collaborative agents emphasize more autonomy and cooperation than learning. They collaborate with other agents in multi-agent environments and may have to negotiate with other agents in order to reach mutually acceptable agreements for users. Unlike collaborative agents, interface agents emphasize more autonomy and learning. They support and provide proactive assistance. They can observe user's actions in the interface and suggest better ways for completing a task for the user. Also, interface agents' cooperation with other agents is typically limited to asking for advice (Ndumu et al. 1997).

Figure 1. Franklin and Grasser's agent taxonomy (Source: Franklin & Grasser. 1996)

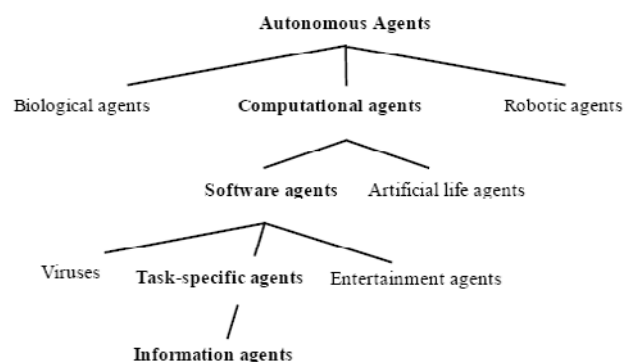

Figure 2. A Part View of Agent Typology Source: Nwana (1996b)

The benefits of interface agents include reducing user's efforts in repetitive work and adapting to their user's preferences and habits. Smart agents are agents that are intelligent, adaptive, and computational (Carley 1998). They are advanced intelligent agents summing up the best capabilities and properties of all presented categories.

This proposed typology highlights the key contexts in which the agent is used in AI literature. Yet Nwana (1996b) argued that agents ideally should do all three equally well, but this is the aspiration rather than the reality. Furthermore, according to Nwana (1996b) and Jennings and Wooldridge (1998), five more agent types could be derived based on the typology, from a panoramic perspective (see Figure 3).

In this proposed typology, mobile agents are autonomous and cooperative software processes capable of roaming wide area networks, interacting with foreign hosts, performing tasks on behalf of their owners (Houmb 2002). Information agents can help us manage the explosive growth of information we are experiencing. They perform the role of managing, manipulating,

or collating information from many distributed sources (Nwana 1996b). Reactive agents choose actions by using the current world state as an index into a table of actions, where the indexing function's purpose is to map known situations to appropriate actions. These types of agents are sufficient for limited environments where every possible situation can be mapped to an action or set of actions (Chelberg 2003). Hybrid agents adopt strength of both the reactive and deliberative paradigms. They aim to have the quick response time of reactive agents for well known situations, yet also have the ability to generate new plans for unforeseen situations (Chelberg 2003). Heterogeneous agents systems refer to an integrated set-up of at least two or more agents, which belong to two or more different agent classes (Nwana 1996b).

CONCLUSION AND FUTURE WORK

This paper explores how ISAs can automate and add value to e-commerce transactions and negotiations. By

Figure 3. A panoramic overview of the different agent types (Source: Jennings & Wooldridge, 1998)

leveraging ISA-based e-commerce systems, companies can more efficiently make decisions because they have more accurate information and identify consumers' tastes and habits. Opportunities and limitations for ISA development are also discussed. Future technologies of ISAs will be able to evaluate basic characteristics of online transactions in terms of price and product description as well as other properties, such as warranty, method of payment, and after-sales service. Also, they would better manage ambiguous content, personalized preferences, complex goals, changing environments, and disconnected parties (Guttman et al. 1998a). Additionally, for the future trend of ISA technology deployment, Nwana (1996a) describes that "Agents are here to stay, not least because of their diversity, their wide range of applicability and the broad spectrum of companies investing in them. As we move further and further into the information age, any information-based organization which does not invest in agent technology may be committing commercial hara-kiri."

KEY TERMS

Agent: A computer system situated in some environment that is capable of autonomous action in this environment to meet its design objective.

Business-to-Business E-Commerce: Electronic transaction of goods or services between businesses as opposed to that between businesses and other groups.

Business-to-Customer E-Commerce: Electronic or online activities of commercial organizations serving the end consumer with products and/or services. It is usually applied exclusively to e-commerce.

Customer-to-Customer E-Commerce: Online transactions involving the electronically-facilitated transactions between consumers through some third party.

Electronic Commerce (E-Commerce): Consists of the buying and selling of products or services over electronic systems such as the Internet and other computer networks. A wide variety of commerce is conducted in this way, including electronic funds transfer, supply chain management, e-marketing, online transaction processing, and automated data collection systems.

Intelligent Software Agent: A software agent that uses Artificial Intelligence (AI) in the pursuit of the goals of its clients.

Ubiquitous Commerce (U-Commerce): The ultimate form of e-commerce and m-commerce in an 'anytime, anywhere' fashion. It involves the use of ubiquitous networks to support personalized and uninterrupted communications and transactions at a level of value that far exceeds traditional commerce.

ISA OPPORTUNITIES AND LIMITATIONS IN E-COMMERCE

Cowan et al. (2002) argued that the human cognitive ability to search for information and to evaluate their usefulness is extremely limited in comparison to those of computers. In detail, it's cumbersome and time-consuming for a person to search for information from limited resources and to evaluate the information's usefulness. They further indicated that while people are able to perform several queries in parallel and are good at drawing parallels and analogies between pieces of information, advanced systems that embody ISA architecture are far more effective in terms of calculation power and parallel processing abilities, particularly in the quantities of material they can process (Cowan et al. 2002). According to Bradshaw (1997), information complexity will continue to increase dramatically in the coming decades. He further contended that the dynamic and distributed nature of both data and applications require that software not merely respond to requests for information but intelligently anticipate, adapt, and actively seek ways to support users.

E-commerce applications based on agent-oriented e-commerce systems have great potential. Agents can be designed using the latest web-based technologies, such as Java, XML, and HTTP, and can dynamically discover and compose E-services and mediate interactions to handle routine tasks, monitor activities, set up contracts, execute business processes, and find the best services (Shih et al., 2003). The main advantages of using these technologies are their simplicity of usage, ubiquitous nature, and their heterogeneity and platform independence (Begin and Boisvert, 2002). XML will likely become the standard language for agent-oriented E-commerce interactions to encode exchanged messages, documents, invoices, orders, service descriptions, and other information. HTTP,

the dominant WWW protocol, can be used to provide many services, such as robust and scalable web servers, firewall access, and levels of security for these E-commerce applications.

Agents can be made to work individually, as well as in a collaborative manner to perform more complex tasks (Franklin and Graesser, 1996). For example, to purchase a product on the Internet, a group of agents can exchange messages in a conversation to find the best deal, can bid in an auction for the product, can arrange financing, can select a shipper, and can also track the order. Multi-agent systems (groups of agents collaborating to achieve some purpose) are critical for large-scale e-commerce applications, especially B2B interactions such as service provisioning, supply chain, negotiation, and fulfillment, etc. The grouping of agents can be static or dynamic depending on the specific need (Guttman et al., 1998b). A perfect coordination should be established for the interactions between the agents to achieve a higher-level task, such as requesting, offering and accepting a contract for some services (Guttman et al., 1998a).

There are several agent toolkits publicly available which can be used to satisfy the customer requirements and ideally they need to adhere to standards which define multi-party agent interoperability. For example, fuzzy logic based intelligent negotiation agents can be used to interact autonomously and consequently, and save human labor in negotiations. The aim of modeling a negotiation agent is to reach mutual agreement efficiently and intelligently. The negotiation agent should be able to negotiate with other such agents over various sets of issues, and on behalf of the real-world parties they represent, i.e. they should be able to handle multi-issue negotiations at any given time.

The boom in e-commerce has now created the need for ISAs that can handle complicated online transactions and negotiations for both sellers and buyers. In

general, buyers want to find sellers that have desired products and services. And they want to find product information and gain expert advice before and after the purchase from sellers, which, in turn, want to find buyers and provide expert advice about their product or service as well as customer service and support. Therefore, there is an opportunity that both buyers and sellers can automate handling this potential transaction by adopting ISA technology. The use of ISAs will be essential to handling many tasks of creating, maintaining, and delivering information on the Web. By implementing ISA technology in e-commerce, agents can shop around for their users; they can communicate with other agents for product specifications, such as price, feature, quantity, and service package, and make a comparison according to user's objective and requirement and return with recommendations of purchases, which can meet those specifications; they can also act for sellers by providing product or service sales advice, and help troubleshoot customer problems by automatically offering solutions or suggestions; they can automatically pay bills and keep track of the payment.

Looking at ISA development from an international stand point, the nature of Internet in developed countries, such as USA, Canada, West Europe, Japan, and Australia, etc. and the consequent evolution of e-commerce as the new model provide exciting opportunities and challenges for ISA-based developments. Opportunities include wider market reach in a timely manner, higher earnings, broader spectrum of target and potential customers, and collaboration among vendors. This ISA-powered e-commerce arena would be different than our traditional commerce, because the traditional form of competition can give way to collaborative efforts across industries for adding value to business processes. This means that agents of different vendors can establish a cooperative relationship to communicate with each other via XML language in order to set up and complete transactions online.

Technically, for instance, if an information agent found that the vendor is in need of more airplane tickets, it would notify a collaborative agent to search for relevant information regarding the ticket in terms of availability, price, and quantity etc. from other sources over the Internet. In this case, the collaborative agent would work with mobile agents and negotiate with other agents working for different vendors and obtain ticket information for its user. It would be able to provide

the user with the result of the search, and, if needed, purchase the tickets for the user if certain requirements can be met. In the meantime, interface agents can monitor the user's reaction and decision behavior, and would provide the user with informational assistance in terms of advice, recommendation, and suggestion for any related and similar transactions.

On the other hand, however, this kind of intelligent electronic communication and transaction is relatively inapplicable in traditional commerce where different competitive vendors are not willing to share information with each other (Maes et al., 1999). The level of willingness in ISA-based e-commerce is, however, somewhat limited due to sociological and ethical factors, which will be discussed later in this paper. In addition, designing and implementing ISA technology is a costly predicament preventing companies from adopting this emerging tool. Companies need to invest a lot of money to get the ISA engine started. Notwithstanding the exciting theoretical benefits discussed above, many companies are still not sure about how much ISA technology can benefit themselves in terms of revenue, ROI, and business influence in the market where other players are yet to adopt this technology to cooperate with each other. Particularly, medium or small size companies are reluctant to embark on this arena mainly due to the factor of cost.

Additionally, lack of consistent architectures in terms of standards and laws also obstructs the further development of ISA technology (He et al., 2003). In detail, IT industry has not yet finalized the ISA standards, as there are a number of proprietary standards set by various companies. This causes a confusion problem for ISAs to freely communicate with each other. Also, related to standards, relevant laws have not surfaced to regulate how ISAs can legally cooperate with each other and represent their human users in the cyber world.

Additionally, ISA development and deployment is not a global perspective (Jennings et al. 1998). Despite the fact that ISA technology is an ad-hoc topic in developed countries, developing countries are not fully aware of the benefits of ISA and therefore have not deployed ISA-based systems on the Web because their e-commerce development levels and skills are not as sophisticated or advanced as those of the developed countries. This intra-national limitation among developed and developing countries unfortunately hinders

agents from freely communicating with each other over the globally connected Internet.

SOCIOLOGICAL AND ETHICAL CHALLENGES

In the preceding sections of this paper, the technical issues involved in agent development have been addressed. However, in addition to these issues, there are also a range of social and cyber-ethical problems, such as trust and delegation, privacy, responsibility, and legal issues, which will become increasingly important in the field of agent technology (Bradshaw 1997; Jennings et al. 1998; Nwana 1996b).

- **Trust and delegation:** For users who want to depend on ISA technology to obtain desired information, they must trust agents which autonomously delegate for users to do the job. It would take time for users to get used to their agents and gain confidence in the agents that work for them. And users have to make a balance between agents continually seeking guidance and never seeking guidance. Users might need to set proper limitations for their agents, otherwise agents might surpass their authorities.
- **Privacy:** In the explosive information society, security is becoming more and more important. Therefore, users must make sure that their agents always maintain their privacy in the course of transactions. Electronic agent security policies may be needed to encounter this potential threat.
- **Responsibility:** Users need to seriously consider how much responsibility the agents need to carry regarding the transaction pitfall. To some extent, agents are rendered responsibility to get the desired product/service for their users. If the users are not satisfied with the transaction result, they may need to redesign or reprogram the agent rather than directly blame the fault on electronic agents.
- **Legal issues:** In addition to responsibility, users should also think about any potential legal issues triggered by their agents, which, for instance, offer inappropriate advice to other agents resulting in liabilities to other people. This would be very challenging to the ISA technology development, and the scenario would be complicated since the current law does not specify which party (the

company who wrote the agent, the company who customized and used the agent, or both) should be responsible for the legal issues.

- **Cyber-ethical issues:** Eichmann (1994) and Etzioni & Weld (1994) proposed the following etiquettes for ISAs which gather information on the Web.
 - Agents must identify themselves;
 - They must moderate the pace and frequency of their requests to some server;
 - They must limit their searches to appropriate servers;
 - They must share information with others;
 - They must respect the authority placed on them by server operators;
 - Their services must be accurate and up-to-date;
 - Safety: they should not destructively alter the world;
 - Tidiness: they should leave the world as they found it;
 - Thrift: they should limit their consumption of scarce resources;
 - Vigilance: they should not allow client actions with unanticipated results.

CONCLUSION AND FUTURE WORK

ISA technology has to confront the increasing complexity of modern information environments. Research and development of ISAs on the Internet is crucial for the development of next generation in open information environments. Sociological and cyber-ethical issues need to be considered for the next generation of agents in e-commerce system, which will explore new types of transactions in the form of dynamic relationships among previously unknown parties (Guttman et al. 1998b). According to Nwana (1996a), the ultimate ISA's success will be the acceptance and mass usage by users, once issues such as privacy, trust, legal, and responsibility are addressed and considered when users design and implement ISA technologies in e-commerce and emerging commerce, such as mobile commerce (M-commerce) and Ubiquitous commerce (U-commerce). It is expected that future research can further explore how ISAs are leveraged in these two newly emerged avenues.

INTRODUCTION

Most people are familiar with the concept of agents in real life. There are stock-market agents, sports agents, real-estate agents, etc. Agents are used to filter and present information to consumers. Likewise, during the last couple of decades, people have developed software agents, that have the similar role. They behave intelligently, run on computers, and are autonomous, but are not human beings.

Basically, an agent is a computer program that is capable of performing a flexible and independent action in typically dynamic and unpredictable domains (Luck, McBurney, Shehory, & Willmott, 2005). Agents are capable of performing actions and making decisions without the guidance of a human. Software agents emerged in the IT because of the ever-growing need for information processing, and the problems concerning dealing and working with large quantities of data.

Especially important is how agents act with other agents in the same environment, and the connections they form to find, refine and present the information in a best way. Agents certainly can do tasks better if they perform together, and that is why the multi-agent systems were developed.

The concept of an agent has become important in a diverse range of sub-disciplines of IT, including software engineering, networking, mobile systems, control systems, decision support, information recovery and management, e-commerce, and many others. Agents are now used in an increasingly wide number of applications — ranging from comparatively small systems such as web or e-mail filters to large, complex systems such as air-traffic control, that have a large dependency on fast and precise decision making.

Undoubtedly, the main contribution to the field of intelligent software agents came from the field of artificial intelligence (AI). The main focus of AI is to build intelligent entities and if these entities sense and act in some environment, then they can be considered agents (Russell & Norvig, 1995). Also, object-oriented programming (Booch, 2004), concurrent object-based systems (Agha, Wegner, and Yonezawa, 1993), and human-computer interaction (Maes, 1994) are fields that constantly drive forward the development of agents.

BACKGROUND

Although the term ‘agent’ is widely used, by many people working in closely related areas, it defies attempts to produce a single universally accepted definition. One of the most broadly used definitions states that “*an agent is an encapsulated computer system that is situated in some environment, and that is capable of flexible, autonomous action in that environment in order to meet its design objectives*” (Wooldridge and Jennings, 1995).

There are three main concepts in this definition: *situatedness*, *autonomy*, and *flexibility*:

- *Situatedness* means that an agent is situated in some environment and that it receives sensory input and performs actions which change that environment in some way.
- *Autonomy* is the ability of an agent to act without the direct intervention of humans. It has control over its own actions and over its internal state. Also, the autonomy implies the capability of learning from experience.

- *Flexibility* means that the agent is able to perceive its environment and respond to changes in a timely fashion; it should be able to exhibit opportunistic, goal-directed behaviour and take the initiative whenever appropriate. In addition, an agent should be able to interact with other agents and humans, thus to be ‘social’.

For some researchers - particularly those interested in AI - the term ‘agent’ has a stronger and more specific meaning than that sketched out above. These researchers generally mean an agent to be a computer system that, in addition to having the properties identified above, is either conceptualized or implemented using concepts that are more usually applied to humans. For example, it is quite common in AI to characterize an agent using mentalistic notions, such as knowledge, belief, intention, and obligation (Wooldridge & Jennings, 1995).

INTELLIGENT SOFTWARE AGENTS

Agents and Environments

An agent collects its percepts through its sensors, and acts upon the environment through its actuators. Thus, the agent is proactive. Its actions in any moment depend on the whole sequence of these inputs up to that moment. A decision tree for every possible percept

sequence of an agent would completely define the agent’s behavior. This would define the function that maps any sequence of percepts to the concrete action – *the agent function*. The program that defines the agent function is called the *agent program*. So, the agent function is a formal description of the agent’s behavior, and the agent program is a concrete implementation of that formalism. (Krcadinac, Stankovic, Kovanovic & Jovanovic, 2007)

To implement all this, we need to have a computing device with appropriate sensors and actuators on which the agent program will run. This is called *agent architecture*. So, an agent is essentially made of two components: the agent architecture and the agent program.

Also, as Russell and Norvig (1995) specify, one of the most sought after characteristics of an agent is its *rationality*. An agent is rational if it always does the action that will lead to the most successful outcome. The rationality of an agent depends on (a) the performance measure that defines what is a good action and what is a bad action, (b) the agent’s knowledge about the environment, (c) the agent’s available actions, and (d) the agent’s percept history.

The Types of Agents

There are several basic types of agents with respect to their structure (Russell & Norvig, 1995):

1. The simplest kind of agents are the *simple reflex agents*. Such an agent only reacts to its current percept, completely ignoring its percept history. When a new percept is received, a rule that maps that percept to an action is activated. Such rules are known as *condition-action rules*.
2. *Model-based reflex agents* are more powerful agents, because they maintain some sort of internal state of the environment that depends on the percept history. For maintaining this sort of information, an agent must know how the environment evolves, and how its actions affect the environment.
3. *Goal-based agents* have some sort of goal information that describes desirable states of the world. Such an agent’s decision making process is fundamentally different, because when a goal-based agent is considering performing an action it is asking itself “would this action make me

Figure 1. Agent and environment

- happy?” along with the standard “what this action will have as a result?”.
4. *Utility-based agents* use a utility function that maps each state to a number that represents the degree of happiness. They are able to perform rationally even in the situations when there are conflicting goals, as well as when there are several goals that can be achieved, but none with certainty.
 5. *Learning agents* do not have a priori knowledge of the environment, but *learn* about it. This is beneficial because these agents can operate in unknown environments and to a certain degree facilitates the job of developers because they do not need to specify their whole knowledge base.

Multi-Agent Systems

Multi-Agent Systems (MAS) are systems composed of multiple autonomous components (agents). They historically belong to *Distributed Artificial Intelligence* (Bond & Gasser, 1998). MAS can be defined as a loosely coupled network of problem solvers that work together to solve problems that are beyond the individual capabilities or knowledge of a single problem solver (Durfee and Lesser, 1989). In a MAS, each agent has incomplete information or capabilities for solving the problem and thus has a limited viewpoint. There is no global system control, the data is decentralized and the computation is asynchronous.

In addition to MAS, there is also the concept of a *multi-agent environment*, which can be seen as an environment that includes more than one agent. Thus, it can be cooperative, or competitive, or a combined one, and creates a setting where agents need to interact (socialize) between each other, either to achieve their individual objectives, or to manage the dependencies that follow from being situated in a common environment. These interactions range from simple semantic interoperation (exchanging comprehensible communications), client-server interactions (the ability to request that a particular action is performed), to rich social interactions (the ability to cooperate, coordinate, and negotiate about a course of action).

Because of the issues due to heterogeneous nature of agents involved in communication (e.g., finding one another), there is also a need for *middle-agents*, which cover cooperation among agents and connect

service providers with service requesters in the agent world. These agents are useful in various roles, such as *matchmakers* or *yellow page agents* that collect and process service offers (“advertisements”), *blackboard agents* that collect requests, and *brokers* that process both (Sycara, Decker, & Williamson, 1997). There are several alternatives to middle agents, such as Electronic Institutions – a framework for Agents’ Negotiation which seeks to incorporate organizational concepts into multi-agent systems. (Rocha and Oliveira, 2001)

Communication among agents is achieved by exchanging messages represented by mutually understandable language (syntax) and containing mutually understandable semantics. In order to find a common ground for communication, an *agent communication language* (ACL) should be used to provide mechanisms for agents to negotiate, query, and inform each other. The most important such languages today are *KQML* (Knowledge Query and Manipulation Language) (ARPA Knowledge Sharing Initiative, 1993) and *FIPA ACL* (FIPA, 1997).

AGENT APPLICABILITY

There are great possibilities for applying multi-agent systems to solving different kinds of practical problems.

- *Auction negotiation model*, as a form of communication, enables a group of agents to find good solutions by achieving agreement and making mutual compromises in case of conflicting goals. Such an approach is applicable to trading systems, where agents act on behalf of buyers and sellers. Financial markets, as well as scheduling, travel arrangement, and fault diagnosing also represent applicable fields for agents.
- Another very important field is *information gathering*, where agents are used to search through diverse and vastly different information sources (e.g., World Wide Web) and acquire relevant information for their users. One of the most common domains is Web browsing and search, where agents are used to adapt the content (e.g., search results) to the users’ preferences and offer relevant help in browsing.
- *Process control software systems* require various kinds of automatic (autonomous) control and re-

action for its processes (e.g. production process). Reactive and responsive, agents perfectly fit the needs of such a task. Example domains in this field include: production process control, climate monitoring, spacecraft control, and monitoring nuclear power plants.

- *Artificial life* studies the evolution of agents, or populations of computer simulated life forms in artificial environments. The goal is to study phenomena found in real life evolution in a controlled manner, hopefully to eliminate some of the inherent limitations and cruelty of evolutionary studies using live animals.
- Finally, *intelligent tutoring systems* often include pedagogical agents, which represent software entities constructed to present the learning content in a user-friendly fashion and monitor the user's progress through the learning process. These agents are responsible for guiding the user and suggesting additional learning topics related to the user's needs (Devedzic, 2006).

Some of the more specific examples of intelligent agent applications include Talaria System, military training, and Mobility Agents. Talaria System (The Autonomous Lookup And Report Internet Agent System) is a multi-agent system, developed for academic purposes at the University of Belgrade, Serbia. It was built as a solution to the common problem of gathering information from diverse Web sites that do not provide RSS feeds for news tracking. The system was implemented using the JADE modeling framework in Java. (Stankovic, Krcadinac, Kovanovic & Jovanovic, 2007) Talaria System is using the advantages of human-agent communication model to improve usability of web sites and to relieve users from annoying and repetitive work. The system provides each user with a personal agent, which periodically monitors the Web sites that the user expressed interest in. The agent informs its user about relevant changes, filtered by assumed user preferences and default relevance factors. Human-agent communication is implemented via email, so that a user can converse with her/his agent in natural language, whereas the agent heuristically interprets concrete instructions from the mail text (e.g., "monitor this site" or "kill yourself").

Simulation and modelling are extensively used in a wide range of military applications, from development, testing and acquisition of new systems and

technologies, to operation, analysis and provision of training, and mission rehearsal for combat situations. The Human Variability in Computer Generated Forces (HV-CGF) project, undertaken on behalf of the UK's Ministry of Defence, developed a framework for simulating behavioral changes of individuals and groups of military personnel when subjected to moderating influences such as caffeine and fatigue. The project was built with the JACK Intelligent Agents toolkit, a commercial Java-based environment for developing and running multiagent applications. Each team member is a rational agent able to execute actions such as doctrinal and non-doctrinal behaviour tactics, which are encoded as JACK agent graphical plans. (Belecheanu et al., 2005)

Mobility Agents is an agent-based architecture that helps a person with cognitive disabilities to travel using public transportation. Agents are used to represent transportation participants (buses and travelers) and to enable notification of bus approaching and arrival. Information is passed to the traveler using a multimedia interface, via a handheld device. Customizable user profiles determine the most appropriate modality of interaction (voice, text, and pictures) based on the user's abilities (Repenning & Sullivan, 2003). This imposes a personal agent to take care that abstract goals, as "go home", are translated into concrete directions. To achieve this, an agent needs to collect information about user-specific locations and must be able to suggest the right bus for the particular user's current location and destination.

FUTURE TRENDS

Future looks bright for this technology as development is taking place within a context of broader visions and trends in IT. The whole growing field of IT is about to drive forward the R&D of intelligent agents. We especially emphasize *the Semantic Web, ambient intelligence, service oriented computing, Peer-to-peer computing* and *Grid Computing*.

The Semantic Web is the vision of the future Web based on the idea that the data on the Web can be defined and linked in such a way that it can be used by machines for the automatic processing and integration (Berners-Lee, Hendler, & Lassila, 2001). The key to achieving this is by augmenting Web pages with descriptions of their content in such a way that it is possible for

machines to reason automatically about that content. The common opinion is that the Semantic Web itself will be a form of intelligent infrastructure for agents, allowing them to “understand” the meaning of the data on the Web (Luck et al., 2005).

The concept of *ambient intelligence* describes a shift away from PCs to a variety of devices which are embedded in our environment and which are accessed via intelligent interfaces. It requires agent-like technologies in order to achieve autonomy, distribution, adaptation, and responsiveness.

Service oriented computing is where MAS could become very useful. In particular, this might involve web services, where the Quality Of Service demands are important. Each web service could be modeled as an agent, with dependencies, and then simulated for observed failure rates.

Peer-to-peer (P2P) computing, presenting networked applications in which every node is in some sense equivalent to all others, tends to become more complex in the future. Auction mechanism design, agent negotiation techniques, increasingly advanced approaches to trust and reputation, and the application of social norms, rules and structures - presents some of the agent technologies that are about to become relevant in the context of P2P computing.

Grid Computing is the high-performance agent-based computing infrastructure for supporting large-scale distributed scientific endeavour. The Grid provides a means of developing eScience applications, yet it also provides a computing infrastructure for supporting more general applications that involve large-scale information handling, knowledge management and service provision. The key benefit of Grid computing is flexibility – the distributed system and network can be reconfigured on demand in different ways as business needs change.

Some considerable challenges have still remained in the agent-based world, such as the lack of sophisticated software tools, techniques and methodologies that would support the specification, development, integration and management of agent systems.

CONCLUSION

Today, research and development in the field of intelligent agents is rapidly expanding. At its core is the concept of autonomous agents interacting with one

another for their individual and/or collective benefit. A number of significant advances have been made over the past two decades in design and implementation of individual autonomous agents, and in the way in which they interact with one another. These concepts and technologies are now finding their way into commercial products and real-world software solutions. Future IT visions share the common need for agent technologies and prove that agent technologies will continue to be of vital importance. It is foreseeable that agents will become the integral part of informational technologies and artificial intelligence in the near future, and that is why they should be kept an eye on.

KEY TERMS

Actuators: Software component and part of the agent used as a mean of performing actions in the agent environment.

Agent Autonomy: Agent's active use of its capabilities to pursue some goal, without intervention by any other agent in the decision-making process used to determine how that goal should be pursued (Barber & Martin, 1999).

Agent Percepts: Every information that an agent receives through its sensors, about the state of the environment or any part of the environment.

Intelligent Software Agent: An encapsulated computer system that is situated in some environment and that is capable of flexible, autonomous action in that environment in order to meet its design objectives (Wooldridge & Jennings, 1995).

Middle-Agents: Agents that facilitate cooperation among other agents and typically connect service providers with service requesters.

Multi-Agent System (MAS): A software system composed of several agents that interact in order to find solutions of complex problems.

Sensors: Software component and part of the agent used as a mean of acquiring information about current state of the agent environment (i.e., agent percepts).

INTRODUCTION

The **Artificial Neural Networks** (ANNs) are based on the behavior of the brain. So, they can be considered as intelligent systems. In this way, the ANNs are constructed according to a brain, including its main part: the neurons. Moreover, they are connected in order to interact each other to acquire the followed intelligence. And finally, as any brain, it needs having memory, which is achieved in this model with their weights.

So, starting from this point of view of the ANNs, we can affirm that these systems are able to learn difficult tasks. In this article, the task to learn is to distinguish between different kinds of **traffic signs**. Moreover, this ANN learning must be done for **traffic signs** that are not in perfect conditions. So, the learning must be robust against several problems like rotation, translation or even vandalism. In order to achieve this objective, an intelligent extraction of information from the images is done. This stage is very important because it improves the performance of the ANN in this task.

BACKGROUND

The **Traffic Sign Classification** (TSC) problem has been studied many times in the literature. This problem is solved in (Perez, 2002, Escalera, 2004) using the correlation between the **traffic sign** and each element of a database, which involves large computational cost. In (Hsu, 2001), Matching Pursuit (MP) is applied in two

stages: training and testing. The training stage finds a set of the best MP filters for each **traffic sign**, while the testing one projects the unknown traffic sign to different MP filters to find the best match. This method also implies large computational cost, especially when the number of elements grows up. In recent works (Escalera, 2003, Vicen, 2005a, Vicen, 2005b), the use of ANNs is studied. The first one studies the combination of the Adaptive Resonance Theory with ANNs. It is applied to the whole image, where many **traffic signs** can exist, which involves that the ANN complexity must be very high to recognize all the possible signs. In the last works, the TSC is constructed using a **preprocessing** stage before the ANN, which involves a computational cost reduction in the classifier.

TSCs are usually composed by two specific stages: the *detection* of **traffic signs** in a video sequence or image and their *classification*. In this work we pay special attention to the classification stage. The performance of these stages highly depends on lighting conditions of the scene and the state of the **traffic sign** due to deterioration, vandalism, rotation, translation or inclination. Moreover, its perfect position is perpendicular to the trajectory of the vehicle, however many times it is not like that. Problems related to the **traffic sign** size are of special interest too. Although the size is normalized, we can find signs of different ones, because the distance between the camera and the sign is variable. So, the classification of a **traffic sign** in this environment is not easy.

The objective of this work is the study of different classification techniques combined with different **pre-processings** to implement an intelligent TSC system. The **preprocessings** considered are shown below and are used to reduce the classifier complexity and to improve its performance. The studied classifiers are the k-Nearest Neighbor (k-NN) and an ANN based method using **Multilayer Perceptrons (MLPs)**. So, this work tries to find which are the best **preprocessings**, the best classifiers and which combination of them minimizes the error rate.

INTELLIGENT TRAFFIC SIGN CLASSIFICATION

An intelligent **traffic sign** classification can be achieved taking into account two important aspects. The first one focus on the extraction of the relevant information of the input **traffic signs**, which can be done adaptively or fixed. The second one is related with the classification core. From the point of view of this part, ANNs can play a great role, because they are able to learn from different environments. So, an intelligent combination of both aspects can lead us to the success in the classification of **traffic signs**.

Traffic Sign Classification System Overview

The TSC system and the blocks that compose it are shown in figure 1. Once the *Video Camera* block takes a

video sequence, the *Image Extraction* block makes the video sequence easy to read and it is the responsible to obtain images. The *Sign Detection and Extraction Stage* extracts all the **traffic signs** contained in each image and generates the small images called blobs, one per possible sign. Figure 1 also shows an example of the way this block works. The *Color Recognition Stage* is the responsible to discern among the different predominant color of the **traffic sign**: blue, red or others. Once the blob is classified according to its predominant color, the *TSC Stage* has the responsibility to recognize the exact type of signal, which is the aim of this work. This stage is divided in two parts: the **traffic sign preprocessing** stage and the TSC core.

Database Description

The database of blobs used to obtain the results presented in this work is composed of blobs with only noise and nine different types of blue **traffic signs**, which belong to the international traffic code. Figure 2.a (Normal Traffic Signs) shows the different classes of **traffic signs** considered in this work, which have been collected by the TSC system presented above. So, they present distortions due to the problems described in previous sections, which are shown in figure 2.b (Traffic Signs with problems). The problems caused by vandalism are shown in the example of class S_8 . The problems related to the blob extraction in the *Sign Detection and Extraction Stage* (not a correct fit in the square image) are shown in the examples of classes S_2 , S_4 and S_9 . Examples of signs with problems of rotation, translation or inclination are those of classes S_4 , S_6 and

Figure 1. Traffic sign classification system

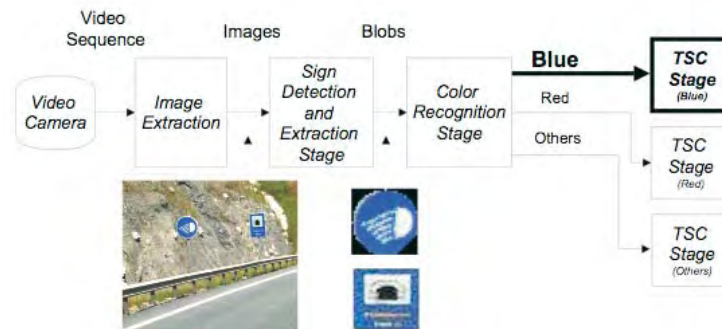

Figure 2. Noise and nine classes of international traffic signs: (a) Normal traffic signs and (b) Traffic signs with problems

S_9 . Finally, the difference of brightness is observed in both parts of figure 2. For example, when the lighting of the blob is high, the vertical row of the example of class S_3 is greater than horizontal row of the example of class S_2 .

Traffic Sign Preprocessing Stage

Each blob presented at the input of the TSC stage contains information of the three-color components: red, green and blue. Each blob is composed of 31×31 pixels. So, the memory required for each blow is 2883 bytes. Due to the high quantity of data, the purpose of this stage is to reduce it and to limit the redundancy of information, in order to improve the TSC performance and to reduce the TSC core computational cost.

The first **preprocessing** made in this stage is the transformation of the color blob ($3 \times 31 \times 31$) to a gray scale blob (31×31) (Paulus, 2003). Consider for the next explanation that \mathbf{M} is a general bidimensional matrix that contains either the gray scale blob or the output of one of the next **preprocessings**:

- **Median filter** (MF) (Abdel, 2004). It is applied to each pixel of \mathbf{M} . A block of $n \times n$ elements that surrounds a pixel of \mathbf{M} is taken, which is sorted in a linear vector. The median value of this vector is selected as the value of the processed pixel. This

preprocessing is usually used to reduce the noise in an image.

- **Histogram equalization** (HE). It tries to enhance the contrast of \mathbf{M} . The pixels are transformed according to a specified image **histogram** (Paulus, 2003). This equalization is usually used to improve the dynamic range of \mathbf{M} .
- **Vertical** (VH) and **horizontal** (HH) **histograms** (Vicen, 2005a, Vicen, 2005b). They are computed with

$$vh_i = \frac{1}{31} \sum_{j=1}^{31} (m_{i,j} > T) \quad , \quad i = 1, 2, \dots, 31 \quad (1)$$

$$hh_j = \frac{1}{31} \sum_{i=1}^{31} (m_{i,j} > T) \quad , \quad j = 1, 2, \dots, 31 \quad (2)$$

respectively, where $m_{i,j}$ is the element of the i -th row and j -th column of the matrix \mathbf{M} and T is the fixed or adaptive threshold of this **preprocessing**. If T is fixed, it is established at the beginning of the **preprocessing**, but if T is adaptive, it can be calculated with the Otsu method (Ng, 2004) or with the mean value of the blob, so both methods are \mathbf{M} -dependent. vh_i corresponds to the ratio of values of column j -th that are greater than T and hh_j corresponds to the ratio of values of row i -th that are greater than T .

Traffic Sign Classification Core

TSC can be formulated as a multiple hypothesis test. Consider that $P(D_i|S_j)$ is the probability of deciding in favor of S_i (decision D_i) when the true hypothesis is S_j , $C_{i,j}$ is the cost associated with this decision and $P(S_j)$ is the prior probability of hypothesis S_j . Then the objective is to minimize a risk function that is given as the average cost \bar{C} , which is defined in (3) for L hypothesis.

$$\bar{C} = \sum_{i=1}^L \sum_{j=1}^L C_{i,j} P(D_i | S_j) P(S_j) \quad (3)$$

The classifier performance can be given as the *total error rate* (P_e) and the *total correct rate* ($P_c = 1 - P_e$) for all the hypothesis (classes).

Traffic Sign Classification Core Based on Statistical Methods: The k -NN

The k -NN approach is a widely-used statistical method (Kisinski, 1975) applied in classification tasks. It assumes that the training set contains M_i points of class S_i and M points in total, so

$$\sum_i M_i = M$$

Then a hypersphere around the observation point \mathbf{x} is taken, which encompasses k points irrespective of their class label. Suppose this sphere, of volume V , contains k_i points of class S_i , then

$$p(\mathbf{x} | S_i) \approx \frac{k_i}{M_i V} \quad (4)$$

provides an approximation to this class-conditional density. The unconditional density can be estimated using

$$p(\mathbf{x}) \approx \frac{k}{MV} \quad (5)$$

while the priors can be estimated using

$$p(S_i) \approx \frac{M_i}{M} \quad (6)$$

Then applying Bayes' theorem (Bishop, 1995), we obtain:

$$p(S_i | \mathbf{x}) = \frac{p(\mathbf{x} | S_i) p(S_i)}{p(\mathbf{x})} \approx \frac{k_i}{k} \quad (7)$$

Thus, to minimize the probability of misclassifying \mathbf{x} , it should be assigned to the class S_i for which the ratio k_i/k is highest. The way to apply this method consists in comparing each \mathbf{x} of the test set with all the training set patterns and deciding which class S_i is the most appropriate one. k denotes the number of patterns that take part in the final decision of classifying \mathbf{x} in class S_i . When a draw exists in the majority voting, the decision is taking using the class of the nearest pattern. So, the results for $k=1$ and $k=2$ are the same.

Traffic Sign Classification Core Based on Neural Networks: The MLP

The Perceptron was developed by F. Rosenblatt (Rosenblatt, 1962) in the 1960s for optical character recognition. The Perceptron has multiple inputs fully connected to an output layer with multiple outputs. Each output y_i is the result of applying a linear combination of the inputs to a non-linear function called activation function. **MLPs** (Haykin, 1999) extend the Perceptron by cascading one or more extra layers of processing elements. These layers are called hidden layers, since their elements are not connected directly to the external world. The expression $I/H_1/\dots/H_n/O$ denotes an **MLP** with I inputs (size of the observation vector \mathbf{x}), h hidden layers with H_h neurons in each one and O outputs (size of the classification vector \mathbf{y}).

Cybenko's theorem (Cybenko, 1989) states that any continuous function $f: \mathfrak{R}^n \rightarrow \mathfrak{R}$ can be approximated with any degree of precision by log-sigmoidal functions. Therefore, MLPs using the log-sigmoidal activation function for each neuron are selected.

Gradient descent with momentum and adaptive learning rate backpropagation algorithm is used to train the **MLPs**, where the *Mean Square Error* (MSE)

criterion is minimized. Moreover, cross-validation is used in order to reduce generalization problems.

RESULTS

The database considered for the experiments is composed of 235 blobs of ten different classes: noise (S_0) and nine classes of **traffic signs** (S_1 - S_9). The database has been divided in three sets: train, validation and test, which are composed of 93, 52 and 78 blobs, respectively, being preprocessed before they are presented to the **TSC** core. The first one is used as the training set for the k -NN and the **MLPs**. The second one is used to stop the **MLP** training algorithm (Bishop, 1995, Haykin, 1999) according to the cross-validation applied during the training. And the last one is used to evaluate the performance of the k -NN and the **MLPs**. Experimental environments characterized by a large dimensional space and a small data set pose generalization problems. For this reason, the **MLPs** training is repeated 10 times with different weights initialization each time and the best **MLP** in terms of P_e estimated with the validation set is selected.

Once the color blobs are transformed to gray scale, three different *combinations of preprocessings* (CPPs) are applied, so each CPP output is 62 elements:

- The first combination (CPP1) applies the VH and HH with an adaptive threshold T calculated with the mean of the blob.
- The second combination (CPP2) applies, in this order, the HE and the VH and HH with an adaptive threshold T calculated with the Otsu method.
- The third combination (CPP3) applies, in this order, the MF, the HE and the VH and HH with a fixed threshold ($T=185$).

For the **TSC** core based on the k -NN, a study of the k parameter is made for the different CPPs considered in the experiments (table 1). The lowest error rate is achieved with CPP3 and $k=1$, which performance is $P_e=6,4\%$ ($P_e=93,6\%$).

For the **TSC** core based on **MLPs**, a study of the number of hidden layers (h) and the number of neurons in each one (H_h) is done.

For the case of one hidden layer ($h=1$), table 2 shows the results for the different CPPs. In this case, the best

performance is obtained with the CPP3 and an **MLP** of 62/62/10, where its error rate is $P_e=2,6\%$ ($P_e=97,4\%$). The CPP2 achieves good performances but they are always lower than in the case of using the CPP3. The use of CPP1 with **MLPs** achieves the worst results of the three cases under study.

The study of the **TSC** core based on an **MLP** with two hidden layers ($h=2$) (table 3) shows that the best combination of the CPPs and $[H_1, H_2]$ for the **MLP** is CPP3 and $[H_1=70, H_2=20]$, respectively. In this case, the best performance achieved is $P_e=1,3\%$ ($P_e=98,7\%$). As occurs for **MLPs** with one hidden layer, the best CPP is the third one and the worst one is the first one.

FUTURE TRENDS

New innovations can be achieved in this research area. The new trends try to improve the **preprocessing** techniques. In this case, advance signal processing can be applied to **TSC**. On the other hand, other **TSC** cores can be used. For instance, classifiers based on Radial Basis Function or Support Vector Machines (Maldonado, 2007) can be applied. Finally, optimization techniques, like **Genetic Algorithms**, have an important role in this research area to find which is the best selection of **preprocessings** of a bank of them.

CONCLUSION

The performances of all the **TSC** designs are quite good, even though when the problems of deterioration, vandalism, rotation, translation, inclination, not a correct fit in the 31x31 blob and variation in size exist in the blobs.

Several combinations of **preprocessings** are used. The best one applies, in this order, the *median filter*, the *histogram equalization* and the *vertical and horizontal histograms* with a fixed threshold ($T=185$).

Concerning the type of classifier, the best **TSCs** are always achieved with **MLPs**. Moreover, the best results are achieved by **MLPs** of two hidden layers. The P_e reduction of the **TSC** core based on a 62/70/20/10 **MLP** ($P_e=1,3\%$) is of 1,3% with respect to the best one achieved with only one hidden layer **MLP** (62/62/10) and 5,1% with respect to the best k -NN ($k=1$) achieved.

Table 1. $P_e(\%)$ versus k parameter for each TSC based on different CPPs and k -NN

| k | 1 | 3 | 4 | 5 | 6 | 7 | 8 | 9 | 10 | 11 | 12 |

KEY TERMS

Artificial Neural Networks (ANNs): A network of many simple processors (“units” or “neurons”) that imitates a biological neural network. The units are connected by unidirectional communication channels, which carry numeric data. Neural networks can be trained to find nonlinear relationships in data, and are used in applications such as robotics, speech recognition, signal processing or medical diagnosis.

Backpropagation Algorithm: Learning algorithm of ANNs, based on minimizing the error obtained from the comparison between the ANN outputs after the application of a set of network inputs and the desired outputs. The update of the weights is done according to the gradient of the error function evaluated in the point of the input space that indicates the input to the ANN.

Classification: The act of distributing things into classes or categories of the same type.

Detection: The perception that something has occurred or some state exists.

Information Extraction: Obtention of the relevant aspects contained in data. It is commonly used to reduce the input space of a classifier.

Pattern: Observation vector that for its relevance is considered as an important example of the input space.

Preprocessing: Operation or set of operations applied to a signal in order to improve some aspects of it.

Interactive Systems and Sources of Uncertainties

INTRODUCTION

Today's e-commerce environment requires that interactive systems exhibit abilities such as autonomy, adaptive and collaborative behavior, and inferential capability. Such abilities are based on the knowledge about users and their tasks to be performed (Raisinghani, Klassen and Schkade, 2001). To adapt users' input and tasks an interactive system must be able to establish a set of assumptions about users' profiles and task characteristics, which is often referred as user models. However, to develop a user model an interactive system needs to analyze users' input and recognize the tasks and the ultimate goals users trying to achieve, which may involve a great deal of uncertainties.

Uncertainty refers to a set of values about a piece of assumption that cannot be determined during a dialog session. In fact, the problem of uncertainty in reasoning processes is a complex and difficult one. Information available for user model construction and reasoning is often uncertain, incomplete, and even vague. The propagation of such data through an inference model is also difficult to predict and control. Therefore, the capacity of dealing with uncertainty is crucial to the success of any knowledge management system.

Currently, a vigorous debate is in progress concerning how best to represent and process uncertainties in knowledge based systems. This debate carries great importance because it is not only related to the construction of knowledge based system but also focuses on human thinking in which most decisions are made under conditions of uncertainty. This chapter presents and discusses uncertainties in the context of user modeling in interactive systems. Some elementary distinctions between different kinds of uncertainties are introduced. The purpose is to provide an analytical overview and perspective concerning how and where uncertainties

arise and the major methods that have been proposed to cope with them.

Sources of Uncertainties

The user model based interactive systems face the problems of uncertainty in the reference rule, the facts, and representation languages. There is no widely accepted definition about the presence of uncertainty in user modeling. However, the nature of uncertainty in a user model can be investigated through its origin. Uncertainty can arise from a variety of sources. Several authors have emphasized the need for differentiating among the types and sources of uncertainty. Some of the major sources are as follows:

(1) The imprecise and incomplete information obtained from the user's input. This type of source is related to the reliability of information, which involves the following aspects:

- Uncertain or imprecise information exists in the factual knowledge (Dutta, 2005). The contents of a user model involve uncertain factors. For instance, the system might want to assert "It is not likely that this user is a novice programmer." This kind of assertion might be treated as a piece of knowledge. But it is uncertain and seems difficult to find a numerical description for the uncertainty in this statement (*i.e.*, no appropriate sample space in which to give this statement statistical meaning, if a statistical method is considered for capturing the uncertainty).
- The default information often brings uncertain factors to inference processes (Reiter, 1980). For example, the stereotype system carries extensive default assumptions about a user. Some assump-

tions may be subject to change as interaction progresses.

- Uncertainty occurs as a result of ill-defined concepts in the observations or due to inaccuracy and poor reliability of the measurement (Kahneman and Tversky, 1982). For example, a user's typing speed could be considered as a measurement for a user's file editing skill. But for some applications it may be questionable.
- The uncertain exception to general assumptions for performing some actions under some circumstances can cause conflicts in reasoning processes.

(2) *Inexact language by which the information is conveyed.* The second source of uncertainty is caused by the inherent imprecision or inexactness of the representation languages. The imprecision appears in both natural languages and knowledge representation language. It has been proposed to classify three kinds of inexactness in natural language (Zwick, 1999). The first is generality, in which a word applies to a multiplicity of objects in the field or reference. For example, the word "table" can apply to objects differing in size, shape, materials, and functions. The second kind of linguistic exactness is ambiguity, which appears when a limited number of alternative meanings have the same phonetic form (e.g., bank). The third is vagueness, in which there are no precise boundaries to the meaning of the word (e.g., old, rich).

In knowledge representation languages employed in user modeling systems, if rules are not expressed in a formal language, their meaning usually cannot be interpreted exactly. This problem has been partially addressed by the theory of approximate reasoning. Generally, a proposition (e.g., fact, event) is uncertain if it involves a continuous variable. Note that an exact assumption may be uncertain (e.g., the user is able to learn this concept), and an assumption that is absolutely certain may be linguistically inexact (e.g. the user is familiar with this concept).

(3) *Aggregation or summarization of information.* The third type of uncertainty source arises from aggregation of information from different knowledge sources or expertise (Bonissone and Tong, 2005). Aggregating information brings several potential problems that are discussed in (Chen and Nocio 1997).

(4) *Deformation while transferring knowledge.* There might be no semantic correspondence between one representation language to another. It is possible that there is even no appropriate representation for certain expertise, for example, the measurement of user's mental workload. This makes the deformation of transformation inevitable. In addition, human factors greatly affect the procedure of information translation. Several tools that use cognitive models for knowledge acquisition have been presented (Jacobson and Freiling, 1988).

CONCLUSION

Generally, uncertainty affects the performance of an adaptive interface in the following aspects and obviously, the management of uncertainty must address all of the following aspects (Chen and Norcio, 2001).

- How to determine the degree to which the premise of a given rule has been satisfied.
- How to verify the extent to which external constraints have been met.
- How to propagate the amount of uncertain information through triggering of a given rule.
- How to summarize and evaluate the findings provided by various rules or domain expertise.
- How to detect possible inconsistencies among the various sources and,
- How to rank different alternatives or different goals.

KEY TERMS

Interactive System: A system that allows dialogs between the computer and the user.

Knowledge Based Systems: A computer system that programmed to imitate human problem-solving

by means of artificial intelligence and reference to a database of knowledge on a particular subject.

Knowledge Representation: The notation or formalism used for coding the knowledge to be stored in a knowledge-based system.

Stereotype: A set of assumptions based on conventional, formulaic, and simplified conceptions, opinions about a user, which is created by an interactive system.

Uncertainties: A potential deficiency in any phase or activity of the modeling process that is due to the lack of knowledge

User Model: A set of information an interactive system infers or collects, which is used to characterize a user's tasks, goals, domain knowledge and preferences, etc. to facilitate human computer interaction.

Intuitionistic Fuzzy Image Processing

Ioannis K. Vlachos

Aristotle University of Thessaloniki, Greece

George D. Sergiadis

Aristotle University of Thessaloniki, Greece

INTRODUCTION

Since its genesis, fuzzy sets (FSs) theory (Zadeh, 1965) provided a flexible framework for handling the indeterminacy characterizing real-world systems, arising mainly from the imprecise and/or imperfect nature of information. Moreover, fuzzy logic set the foundations for dealing with reasoning under imprecision and offered the means for developing a context that reflects aspects of human decision-making. Images, on the other hand, are susceptible of bearing ambiguities, mostly associated with pixel values. This observation was early identified by Prewitt (1970), who stated that “a pictorial object is a fuzzy set which is specified by some membership function defined on all picture points”, thus acknowledging the fact that “some of its uncertainty is due to degradation, but some of it is inherent”. A decade later, Pal & King (1980) (1981) (1982) introduced a systematic approach to fuzzy image processing, by modelling image pixels using FSs expressing their corresponding degrees of brightness. A detailed study of fuzzy techniques for image processing and pattern recognition can be found in Bezdek et al and Chi et al (Bezdek, Keller, Krisnapuram, & Pal, 1999) (Chi, Yan, & Pham, 1996).

However, FSs themselves suffer from the requirement of *precisely* assigning degrees of membership to the elements of a set. This constraint raises some of the flexibility of FSs theory to cope with data characterized by uncertainty. This observation led researchers to seek more efficient ways to express and model imprecision, thus giving birth to higher-order extensions of FSs theory.

This article aims at outlining an alternative approach to digital image processing using the apparatus of Atanassov's intuitionistic fuzzy sets (A-IFSs), a simple, yet efficient, generalization of FSs. We describe heuristic and analytic methods for analyzing/synthesizing images to/from their intuitionistic fuzzy components

and discuss the particular properties of each stage of the process. Finally, we describe various applications of the intuitionistic fuzzy image processing (IFIP) framework from diverse imaging domains and provide the reader with open issues to be resolved and future lines of research to be followed.

BACKGROUND

From the very beginning of their development, FSs intrigued researchers to apply the flexible fuzzy framework in different domains. In contrast with ordinary (crisp) sets, FSs are defined using a characteristic function, namely the *membership function*, which maps elements of a universe to the unit interval, thereby attributing values expressing the *degree of belongingness* with respect to the set under consideration. This particular property of FSs theory was exploited in the context of digital image processing and soon turned out to be a powerful tool for handling the inherent uncertainty carried by image pixels. The importance of fuzzy image processing was rapidly acknowledged by both theoreticians and practitioners, who exploited its potential to perform various image-related tasks, such as contrast enhancement, thresholding and segmentation, de-noising, edge-detection, and image compression.

However, and despite their vast impact to the design of algorithms and systems for real-world applications, FSs are not always able to directly model uncertainties associated with imprecise and/or imperfect information. This is due to the fact that their membership functions are themselves crisp. These limitations and drawbacks characterizing most ordinary fuzzy logic systems (FLSs) were identified and described by Mendel & Bob John (2002), who traced their sources back to the uncertainties that are present in FLSs and arise from various factors. The very meaning of words that are used in the antecedents and consequents of FLSs can

be uncertain, since some words may often mean different things to different people. Moreover, extracting the knowledge from a group of experts who do not all agree, leads in consequents having a histogram of values associated with them. Additionally, data presented as inputs to an FLS, as well as data used for its tuning, are often noisy, thus bearing an amount of uncertainty. As a result, these uncertainties translate into additional uncertainties about FS membership functions. Finally, Atanassov et al. (Atanassov, Koshelev, Kreinovich, Rachamreddy & Yasemis, 1998) proved that there exists a fundamental justification for applying methods based on higher-order FSs to deal with everyday-life situations. Therefore, it comes as a natural consequence that such an extension should also be carried in the field of digital image processing.

THE IFIP FRAMEWORK

In quest for new theories treating imprecision, various higher-order extensions of FSs were proposed by different scholars. Among them, A-IFSs (Atanassov, 1986) provide a simple and flexible, yet solid, mathematical framework for coping with the intrinsic uncertainties characterizing real-world systems. A-IFSs are defined using two characteristic functions, namely the *membership* and the *non-membership* that do not necessarily sum up to unity. These functions assign to elements of the universe corresponding *degrees of belongingness* and *non-belongingness* with respect to a set. The membership and non-membership values induce an *indeterminacy index*, which models the *hesitancy* of deciding the degree to which an element satisfies a particular property. In fact, it is this additional degree of freedom that provides us with the ability to efficiently model and minimize the effects of uncertainty due to the imperfect and/or imprecise nature of information.

Hesitancy in images originates out of various factors, which in their majority are caused by inherent weaknesses of the acquisition and the imaging mechanisms. Distortions occurred as a result of the limitations of the acquisition chain, such as the quantization noise, the suppression of the dynamic range, or the nonlinear behavior of the mapping system, affect our certainty regarding the “*brightness*” or “*edginess*” of a pixel and therefore introduce a degree of hesitancy associated with the corresponding pixel. Moreover, dealing with “*qualitative*” rather than “*quantitative*” properties of images is one

of the sound advantages of fuzzy-based techniques. Qualitative properties describe in a more natural and human-centric manner image attributes, such as the “*contrast*” and the “*homogeneity*” of an image region, or the “*edginess*” of a boundary. However, as already pointed out, these terms are themselves imprecise and thus they additionally increase the uncertainty of image pixels. It is therefore a necessity, rather than a luxury, to employ A-IFSs theory to cope with the uncertainty present in real-world images.

In order to apply the IFIP framework, images should first be expressed in terms of elements of A-IFSs theory. Analyzing and synthesizing digital images to and from their corresponding intuitionistic fuzzy components is not a trivial task and can be carried out using either heuristic or analytic approaches.

Heuristic Modelling

As already stated, the factors introducing hesitancy in real-world images can be traced back to the acquisition stage of imaging systems and involve pixel degradation, mainly triggered by the presence of quantization noise generated by the A/D converters, as well as the suppression of the dynamic range caused by the imaging sensor. A main effect of quantization noise in images is that there exist a number of gray levels with zero, or almost zero, frequency of occurrence, while gray levels in their vicinity possess high frequencies. This is due to the fact that a gray level g in a digital image can be either $(g+1)$ or $(g-1)$ without any appreciable change in the visual perception.

An intuitive and heuristic approach to the modeling of the aforementioned sources of uncertainty in the context of A-IFSs was proposed by Vlachos & Sergiadis (Vlachos & Sergiadis, 2005) (Vlachos & Sergiadis, 2007 d) for gray-scale images, while an extension to color images was presented in Vlachos & Sergiadis (Vlachos & Sergiadis, 2006). The underlying idea involves the application of the concept of the *fuzzy histogram* of an image, which models the notion of the gray level “*approximately g*”. The fuzzy histogram takes into account the frequency of neighboring gray levels to assess the frequency of occurrence of the gray level under consideration. Consequently, a quantitative measure of the quantization noise can be calculated as the normalized absolute difference between the ordinary (crisp) and fuzzy histograms.

Finally, to further incorporate the additional distortion factors into the calculation of hesitancy, parameters are employed that model the influence of the dynamic range suppression and the fact that lower gray levels are more prone to noise than higher ones.

Analytic Modelling

The analytic approach offers a more generic treatment to hesitancy modelling of digital images, since

it does not require an a priori knowledge of the system characteristics, nor a particular pre-defined image acquisition model. Generally, it consists of sequential operations that primarily aim to optimally transfer the image from the pixel domain (PD) to the intuitionistic fuzzy domain (IFD), where the appropriate actions will be performed, using the fuzzy domain (FD) as an intermediate step. After the modification of the membership and non-membership components of the image in the IFD, an inverse procedure is carried out

Figure 1. Overview of the analytic IFIP framework

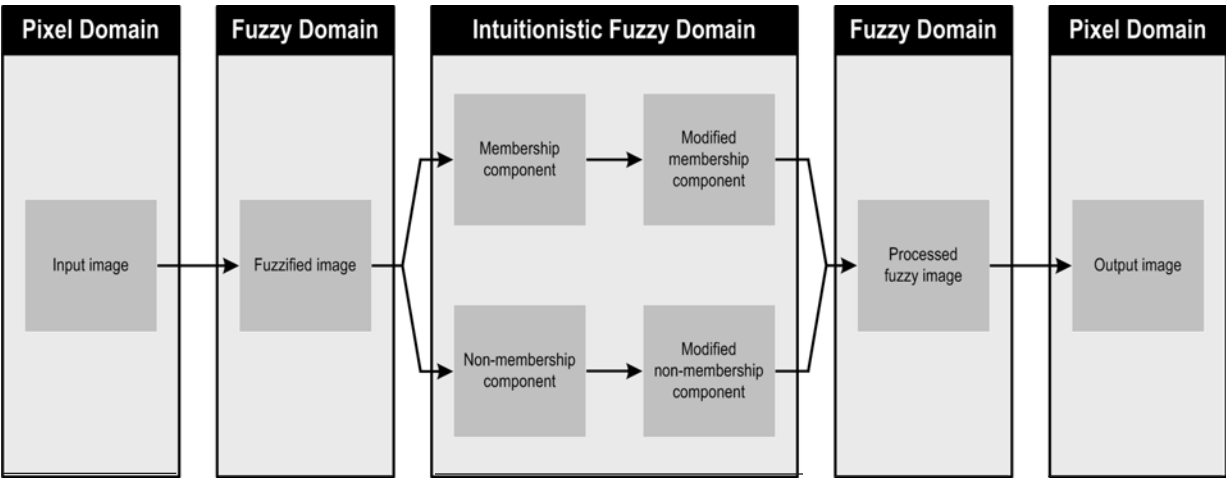

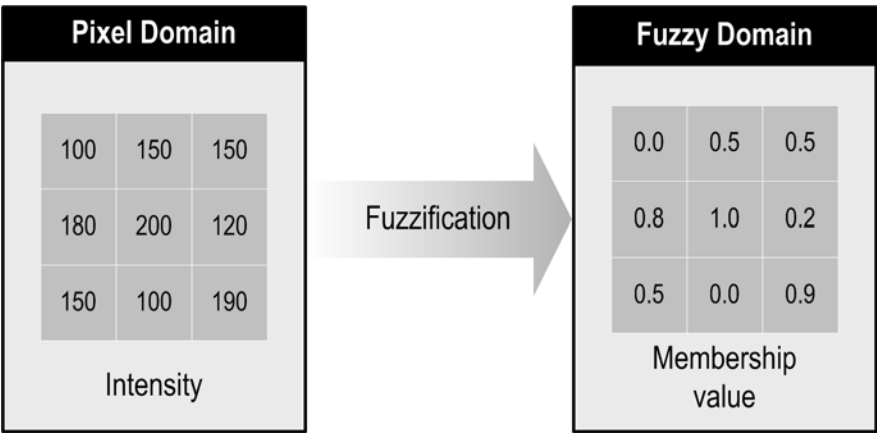

Figure 2. The process of fuzzification (from image properties to membership functions)

for transferring the image back to the PD. A block diagram illustrating the analytic modelling is given in Figure 1. Details on each of the aforementioned stages of IFIP are provided below.

Fuzzification

It constitutes the first stage of the IFIP framework, which assigns degrees of membership to image pixels with respect to an image property, such as “*brightness*”, “*homogeneity*”, or “*edginess*”. These properties are application dependent and also determine the operations to be carried out in the following stages of the IFIP framework. For the task of contrast enhancement one may consider the “*brightness*” of gray levels and construct the corresponding FS “*Bright pixel*” or “*Dark pixel*” using different schemes that range from simple intensity normalization to more complex approaches involving knowledge extracted from a group of human experts (Figure 2).

Intuitionistic Fuzzification

Intuitionistic fuzzification is one of the most important stages of the IFIP architecture, since it involves the construction of the A-IFS that represents the image properties in the IFD. The analytic approach allows for an automated modelling of the hesitancy carried by image pixels, by rendering image properties directly from the FS obtained in the fuzzification stage through the use of *intuitionistic fuzzy generators* (Bustince, Kacprzyk & Mohedano, 2001). In order to construct an A-IFS that efficiently models a particular image property, tunable parametric intuitionistic fuzzy generators are utilized.

The underlying statistics of images are closely related to and soundly affect the process of hesitancy modelling. Different parameter values of the intuitionistic fuzzy generators produce different A-IFSs and therefore alternative representations of the image in the IFD are possible. Consequently, an optimization criterion should be employed, in order to select the parameter set that derives the A-IFS that optimally models the hesitancy of pixels from the multitude of possible representations. Such a criterion, that also encapsulates the image statistics, is the intuitionistic fuzzy entropy (Burillo & Bustince, 1996) (Szmidt & Kacprzyk, 2001) of the image under consideration. Therefore, the set of parameters that produce the A-IFS with the maximum

intuitionistic fuzzy entropy is considered as optimal. We refer to this process of selection as the *maximum intuitionistic fuzzy entropy principle* (Vlachos & Sergiadis, 2007 d). The optimal parameter set is then used to construct membership and non-membership functions corresponding to the intuitionistic fuzzy components of the image in the IFD. This procedure is schematically illustrated in Figure 3.

Modification of Intuitionistic Fuzzy Components

It involves the actual processing of the intuitionistic fuzzy components of the image with respect to a particular property. Depending on the desired image task one is about to perform, suitable intuitionistic fuzzy operators are applied to both membership and non-membership functions.

Intuitionistic Defuzzification

After obtaining the modified intuitionistic fuzzy components of the image, it is required that these components should be combined to produce the processed image in the FD. This procedure involves the embedding of hesitancy into the membership function. To carry out this task, we utilize suitable parametric intuitionistic fuzzy operators that de-construct an A-IFS into an FS. It should be stressed out that the final result soundly depends on the selected parameters of the aforementioned operators. Therefore, optimization criteria, such as the *maximization of the index of fuzziness* of the image, are employed to select the overall optimal parameters with respect to the considered image operation.

Defuzzification

The final stage of the IFIP framework involves the transfer of the processed fuzzy image into the PD. Depending on the desired image operation, various functions may be applied to carry out this task.

Applications

The IFIP architecture has been successfully applied to many image processing problems. Vlachos & Sergiadis (2007 d) exploited the potential of the framework in order to perform contrast enhancement to low-con-

trusted images. Different approaches were introduced, namely the intuitionistic fuzzy contrast intensification and the intuitionistic fuzzy histogram hyperbolization (IFHH). An extension of the IFHH technique to color images was proposed in Vlachos & Sergiadis (Vlachos & Sergiadis, 2007 b). Additionally, the effects of employing different intuitionistic fuzzification and intuitionistic defuzzification schemes to the performance of contrast enhancement algorithms was thoroughly studied and investigated in Vlachos & Sergiadis (2007)

(2007 d) and (2006 b), respectively. Application of A-IFSs theory to edge detection was also demonstrated in Vlachos & Sergiadis (Vlachos & Sergiadis, 2007 d), based on intuitionistic fuzzy similarity measures. The problem of image thresholding and segmentation under the context of IFIP, was also addressed (Vlachos & Sergiadis, 2006 a) using novel intuitionistic fuzzy information measures. Under the general framework of IFIP, the notions of the intuitionistic fuzzy histograms of a digital image were introduced (Vlachos

Figure 3. The process of intuitionistic fuzzification

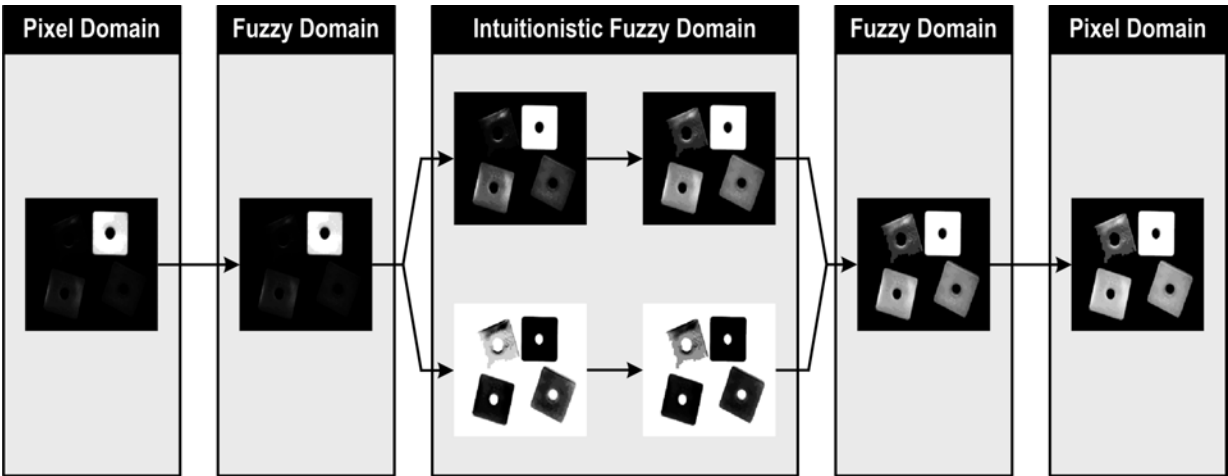

Figure 4. The stages of the IFIP framework for contrast enhancement

& Sergiadis, 2007 c) and their application to contrast enhancement was demonstrated (Vlachos & Sergiadis, 2007 a). Finally, the IFIP architecture was successfully applied in mammographic image processing (Vlachos & Sergiadis, 2007 d). Figure 4 illustrates the stages of IFIP in the case of the IFHH approach.

FUTURE TRENDS

Even though higher-order FSs have been widely applied to decision-making and pattern recognition problems, it seems that their application in the field of digital image processing is just beginning to develop. As a newly-introduced approach, the IFIP architecture remains a suggestively and challenging open field for future research. Therefore, it is expected that the IFIP framework will attract the interest of theoreticians and practitioners in the near future.

The proposed IFIP context bases its efficiency in the ability of A-IFSs to capture and render the hesitancy associated with image properties. Consequently, the analysis and synthesis of images in terms of elements of A-IFSs theory plays a key role in the performance of the framework itself. Therefore, the stages of intuitionistic fuzzification and defuzzification need to be further studied from an application point of view, to provide meaningful ways of extracting and embedding hesitancy from and to images. Finally, the IFIP architecture should be extended to image processing task handled today by FS theory, in order to investigate and evaluate its advantages and particular merits.

CONCLUSION

This article describes an intuitionistic fuzzy architecture for the processing of digital images. The IFIP framework exploits the potential of A-IFSs to efficiently model the uncertainties associated with image pixels, as well as with the definitions of their properties. The proposed methodology provides alternative approaches for analyzing/synthesizing images to/from their intuitionistic fuzzy components. Application of the IFIP framework to diverse imaging domains demonstrates its efficiency compared to traditional image processing techniques. It is expected that the proposed context will provide theoretician and practitioners with an alternative and

challenging way to perceive and deal with real-world image processing problems.

KEY TERMS

Crisp Set: A set defined using a characteristic function that assigns a value of either 0 or 1 to each element of the universe, thereby discriminating between members and non-members of the crisp set under consideration. In the context of fuzzy sets theory, we often refer to crisp sets as “classical” or “ordinary” sets.

Defuzzification: The inverse process of fuzzification. It refers to the transformation of fuzzy sets into crisp numbers.

Fuzzification: The process of transforming crisp values into grades of membership corresponding to fuzzy sets expressing linguistic terms.

Fuzzy Logic: Fuzzy logic is an extension of traditional Boolean logic. It is derived from fuzzy set theory and deals with concepts of partial truth and reasoning that is approximate rather than precise.

Fuzzy Set: A generalization of the definition of the classical set. A fuzzy set is characterized by a membership function, which maps the members of the universe into the unit interval, thus assigning to elements of the universe degrees of belongingness with respect to a set.

Image Processing: Image processing encompasses any form of information processing for which the input is an image and the output an image or a corresponding set of features.

Intuitionistic Fuzzy Index: Also referred to as “hesitancy margin” or “indeterminacy index”. It represents the degree of indeterminacy regarding the assignment of an element of the universe to a particular set. It is calculated as the difference between unity and the sum of the corresponding membership and non-membership values.

Intuitionistic Fuzzy Set: An extension of the fuzzy set. It is defined using two characteristic functions,

the membership and the non-membership that do not necessarily sum up to unity. They attribute to each individual of the universe corresponding degrees of belongingness and non-belongingness with respect to the set under consideration.

Membership Function: The membership function of a fuzzy set is a generalization of the characteristic

function of crisp sets. In fuzzy logic, it represents the degree of truth as an extension of valuation.

Non-Membership Function: In the context of Atanassov's intuitionistic fuzzy sets, it represents the degree to which an element of the universe does not belong to a set.

Knowledge Management Systems Procedural Development

INTRODUCTION

The success of the organisations is increasingly dependant on the knowledge they have, to the detriment of other traditionally decisive factors as the work or the capital (Tissen, 2000). This situation has led the organisations to pay special attention to this new intangible item, so numerous efforts are being done in order to conserve and institutionalise it.

The Knowledge Management (KM) is a recent discipline replying this increasing interest; however, and despite its importance, this discipline is currently in an immature stage, as none of the multiple existing proposals for the development of Knowledge Management Systems (KMS) achieve enough detail for perform such complex task.

In order to palliate the previous situation, this work presents a methodological framework for the explicit management of the knowledge. The study has a formal basis for achieving an increased level of detail, as all the conceptually elements needed for understanding and representing the knowledge of any domain are identified. The requested descriptive character is achieved when basing the process on these elements and, in this way, the development of the systems could be guided more effectively.

BACKGROUND

During the last years numerous methodological frameworks for the development of KMS have arisen, the

most important of which are the ones of Junnarkar (1997), Wiig et al (1997), Daniel et al (1997), Holsapple and Joshi (1997), Liebowitz and Beckman (Liebowitz, 1998; Beckman, 1997), Stabb and Schnurr (1999), Tiwana (2000) and Maté et al (2002). Nevertheless, the existing proposals do not satisfy adequately the needs of the organisation knowledge (Rubenstein-Montano, 2001; Andrade, 2003) due to their immaturity, mainly based on the following aspects:

1. The research efforts have been mainly focused on the definition of a process for KMS development, ignoring instead the study of the object to be managed: the knowledge.
2. The definition of such process has eluded in most of the cases the human factor and it has been restricted only to the technological viewpoint of the KM.

The first aspect regards the necessary study of the knowledge as basis for the definition of the Corporate Memory structure; this study should identify (i) the type of knowledge that has to be included in that repository and (ii) their descriptive properties for the Corporate Memory to include all the features of the knowledge items that it stores. The definition of that structure would enable also the definition of a descriptive process for creating KMS by using the different characteristics and types of knowledge.

However, and despite the influence that the object to be managed has on the management process, only the Wiig (1997) proposal pays attention to its study. Such

proposal identifies a small set of descriptors that support the formalisation (making explicit) of the knowledge although, (i) its identification does not result from an exhaustive study and (ii) it does not enable a complete formalisation as it is solely restricted to some generic properties.

The second step suggests that the whole process for KMS development should consider the technological as well as the human vision. The first one is focused on how obtaining, storing and sharing the relevant knowledge that exists within an organisation, by creating the Corporate Memory and the computer support system. The second vision involves, not only the creation of a collaborative atmosphere within the organisation in order to achieve the involvement of the workers in the KM program, but also the tendency to share their knowledge and use the one already provided by other members.

Despite the previous fact, the vast majority of the analysed approaches are solely focused on the technological KM viewpoint, which jeopardises the success of a KMS (Andrade, 2003). In fact, among the previously mentioned proposals, only the Tiwana (2000) proposal explicitly considers the human viewpoint by including a specific phase for it.

As a result of both aspects, the current proposals are restricted to a set of generic guides for performing KM, which is quite different from the formal and detailed vision that is being demanded. In other words, the current approaches indicate *what to do* but *not how to do it* (prescriptive viewpoint against descriptive/procedural viewpoint). In this scenario the developers of this type of systems have to elaborate their own *ad hoc* approach, achieving results that only depend on the experience and the capabilities of the development team.

DEVELOPMENT FOR KNOWLEDGE MANAGEMENT SYSTEMS

This section presents a methodological framework for the explicit KM that solves the previously mentioned problems. A study of the object to be managed has been performed for obtaining a knowledge formalisation schema, i.e., for knowing the relevant knowledge items and the characteristics/properties that should be made explicit. Using the results achieved after this study a methodological framework for KMS creation has been defined. Both aspects are following discussed.

Proposed Formalisation Schema

The natural language is the language par excellence for sharing knowledge. Due to this, a good identification of all the necessary elements for conceptualising (understanding) the knowledge of any domain (and therefore those for whom the respective formalisation mechanisms must be provided) can be done from the analysis of the different grammatical categories of the natural language: nouns, adjectives, verbs, adverbs, locutions and other linguistic expressions. This study, whose detailed description and applications have been described in several works (Andrade, 2006; Andrade, 2008), reveals that all the identified conceptual elements can be put into the following knowledge levels according to their function within the domain:

- **Static.** It regards the structural or operative knowledge domain, meaning domain facts that are true and that can be used in some operations as concepts, properties, relationships and constraints.
- **Dynamic.** It is related to the performance of the domain, that is, functionality, action, process or control: inferences, calculations and step sequence. This level can be divided into two sublevels:
 - **Strategic.** It includes what to do, when and in what order (i.e., step factorisation).
 - **Tactical.** It specifies how and when obtaining new operative knowledge (i.e., the description of a given step).

Every one of these levels approaches a different fragment of the organisation knowledge, although they all are obviously interrelated; in fact, the strategic level controls the tactical one, as for every last level/elemental step (strategic knowledge) the interferences and calculi must be indicated (tactical knowledge). Also the level of the operative knowledge is controlled by the other two, as it specifies how, not only the bifurcation points or execution alternatives are decided (strategic knowledge), but also how interferences and calculi are done (tactical knowledge).

Therefore, a KMS must provide support to all these levels. As it can be observed at Table 1, the main formalisation schema has been divided, on one hand, into several individual schemas corresponding to each one of the identified knowledge levels and, on the other, into

Table 1. Components defined for every identified schema

| Schemas | | Components |
|---------|-----------|---------------------------------|
| Common | | Catalogue of terms |
| Dynamic | Strategic | Catalogue of non terminal steps |
| | | Catalogue of terminal steps |
| | Tactical | Catalogue of tactical steps |
| Static | Operative | Catalogue of concepts |
| | | Catalogue of relationships |
| | | Catalogue of properties |

a common one for the three levels, providing the global vision of the organisation knowledge. Therefore, the knowledge formalisation involves a dynamic schema including the strategic and tactical individual schemas, a dynamic schema including an operative schema, and a common schema, for describing the common aspects regardless the level. Every individual schema is also constituted by some components.

The catalogue of terms is a common component for the schemas, providing synonyms and abbreviations for identifying every knowledge asset within the organisation. The strategic schema describes the functional splitting of every KMS operation and also each identified step. As the description varies when the step is terminal or not (elemental step), two different components are needed for including all the characteristics of this level. The approach—procedural or algorithmic, for instance—should be described with detail for every asset included into the catalogue of terminal steps. All this information is included at the catalogue of tactical steps. Lastly, the static schema is made up of the catalogue of concepts—including the identified concepts and their description—, the catalogue of relationships—describing the identified relationships and their meaning—and the catalogue of properties—referring the properties of the previously mentioned concepts and relationships—.

The detailed description of this study, together with the descriptors of every component, can be found in (Andrade, 2008).

PROPOSED METHODOLOGICAL FRAMEWORK

The proposed process, whose basic structure is shown in Figure 1, has been elaborated bearing in mind the problems detected at the KM discipline and already mentioned throughout the present work.

As it can be noticed in the previous figure, this process includes the following phases:

1. Setting-up of the KM commission: the direction defines a KM commission for tracking and performing the KM project.
2. Scope identification. The problem to be approached would be specified by means of determining on where the present cycle of the KM project must have a bearing. In order to achieve this, the framework proposes the use of the SWOT analysis (Strengths, Weaknesses, Opportunities, Tricks), together with the proposal of Zack (1999).
3. Knowledge acquisition, including:

3.1. Identification of knowledge domains. The knowledge needs regarding the approached subject area are determined by means of different meetings involving the development team, the KM committee and the people responsible of every operation to be performed.

3.2. Capture of the relevant knowledge. The obtaining of all the possible knowledge related with the

Figure 1. Structure of the proposed process

operation approached is based on the identified domains. This is done by means of:

- (a) Identifying where the knowledge lies in. The KM commission is in charge of identifying and providing the human and non human knowledge sources that are going to be analysed.
- (b) Determining the knowledge that has to be captured. As in the previous epigraph, it should be necessary to bear in mind the strategic, tactical and operative knowledge.
- (c) Knowledge obtaining.

Obviously, when all the knowledge that is needed does not exist at the organisation it should be generated or imported.

4. Knowledge assimilation, comprising:

4.1. Knowledge conceptualisation. Its goal is the comprehension of the captured knowledge. It is recommended to start with the strategic knowledge for subsequently focusing on the tactical knowledge. As the strategic and tactical elements are understood, it would be necessary to assimilate arisen elements of the operative level.

4.2. Knowledge representation. The relevant knowledge has to be made explicit and formalised, according to the components (Andrade, 2008) summarised at Table 1. This is one of the main distinguishing

points of the proposal presented here, as the proposed formalisation schema indicates the specific descriptors needed for a correct and complete formalisation of the knowledge.

5. Knowledge consolidation, including:

5.1. Knowledge verification. In order to detect failures and omissions related with the represented knowledge it should be considered:

- (a) Generic aspects. It has to be checked that any knowledge element (strategic, tactical and operative) is included into the catalogue of terms, that any term included there has been made explicit according to the type of knowledge and, that all the fields are completed.
- (b) Strategic aspects. It should be verified that (i) any decision regarding an execution is made according to the existing operative knowledge, (ii) any last level step is associated to an existing tactical knowledge and, (iii) any non terminal step is correctly split. All the previous facts would be achieved by checking the accordance between the split tree and the content of the formalisation schema of the terminal strategic knowledge.
- (c) Tactical aspects. It should be verified that: (i) the whole of the tactical knowledge is used in some of the last level steps of the strategic knowledge and that any operative knowledge related to the tactical knowledge is available. In order to achieve

this, the operative knowledge items will be represented as nodes within a knowledge map. This type of maps enable the graphic visualisation of how new elements are obtained from the existing ones. Once the map has been done, it should be scoured for checking that the whole of the operative knowledge has been included.

- (d) Operative aspects. It should be confirmed that:
 - (i) there are not isolated concepts, (ii) there are not attributes unrelated to a concept or to a relationship, (iii) there are not relationships associating non existing concepts or relationships and (iv) the whole of the operative knowledge is used in some of the tactical knowledge and/or in the decision making of the flow control of the strategic knowledge. In order to perform the three first verifications, a relationships diagram will be elaborated for graphically showing the existing relationships among the different elements of the operative knowledge. The syntax of this type of diagrams is analogous to the one of the class diagrams used in the methodologies of object-oriented software development. The verification of the last proposal will be done by using a knowledge map; the execution structures included into the content of the formalisation schema for the strategic knowledge of last level related to every process (the remaining inferior levels are included into the superior one) will be also used in this verification. With these two mentioned graphic representations it could be verified that every operative element is included into at least one of the representations.

5.2. Knowledge validation. In order to verify the knowledge represented and verified, the development team, the KM commission and the involved parts will revise:

- (a) The knowledge splitting tree
 - (b) The knowledge map
 - (c) The relationship diagram
 - (d) The functional splitting tree
 - (e) The content of the formalisation schema
6. Creation of the support system, which is divided into:

6.1. Definition of the incorporation mechanisms. The KM commission and the development team determine the adequacy of the incorporation type (passive, active or their combination) according to criteria such as financial considerations or stored knowledge.

6.2. Definition of the notification mechanisms. The KM commission and the development team will establish the most suitable method for notifying the newly included knowledge. The notification can be passive or active; even the absence of notification could be considered.

6.3. Definition of the mechanisms for knowledge localisation. Several alternatives, such as the need of including intelligent searches or meta-searches, are evaluated.

6.4. Development of the KM support system. It will be necessary to define and to implement the corporate memory, the communication mechanisms and the applications for collaboration and team work.

6.5. Population of the corporate memory. Once the KM system has been developed. The knowledge captured, assimilated and consolidated will be included into the corporate memory.

7. Creation of the collaboration environment. The main goal of this phase is to promote and to improve the contribution of knowledge and its subsequent use by the organisation. It should be borne in mind the risk that involves the use of an unsuitable organisation culture or of inadequate tools for promotion and reward. The following strategies should be followed instead:

- Considering the employee worth according his/her knowledge contribution to the organisation
- Supporting and awarding the use of the organisational existing knowledge
- Promoting the relaxed dialogue among employees from different domains
- Promoting a good atmosphere among the employees
- Committing all the employees

FUTURE TRENDS

As it has been indicated, the KM discipline remains in an immature stage due to an inadequate viewpoint: the absence of a strict study for determining the relevant

knowledge and the characteristics that should be supported. Such situation has led to an important detail shortage of the existing proposals for KMS development, currently dependant solely from the individual good work of the developers.

The present proposal means a new viewpoint for developing this type of systems. However, it still remains a lot to do. As the authors are aware of the high grade of bureaucracy that might be needed for specifically following the present proposal, it should be expedited and characterised for specific domains. Nevertheless, this viewpoint could be considered as the key for achieving specific ontologies for KM in every domain.

CONCLUSION

This article has presented a methodological framework for the development of KMS that, differently from the existing proposals, is based on the strict study of the knowledge to be managed. This characteristic has provided the system with a higher procedural level of detail than the current proposals, as the elements conceptually needed for understanding and representing the knowledge of any domain have been identified and formalised.

KEY TERMS

Commission of Knowledge Management: Team in charge of the Knowledge Management project.

Corporate Memory: Physical and persistent storage of the knowledge in an organisation. Its structure is determined by the knowledge formalisation schema.

Knowledge: Pragmatic level of information resulting from the combination of the information received with the individual experience.

Knowledge Formalisation Schema: Set of attributes for describing and formalising the knowledge.

Knowledge Management: Discipline that tries to suitably provide the adequate information and knowledge to the people indicated, whenever and how they need them. In such way these people will have all the necessary elements for best performing their tasks.

Knowledge Management System: System for managing knowledge in organizations, supporting the addition, storage, notification and localization of expertise and knowledge.

Methodological Framework: Approach for making explicit and structuring how a given task is performed.

Knowledge Management Tools and Their Desirable Characteristics

INTRODUCTION

The Knowledge Management (KM) is a recent discipline that was born under the idea of explicitly managing the whole existing knowledge of a given organisation (Wiig, 1995) (Wiig et al., 1997). More specifically, the KM involves providing the people concerned with the right information and knowledge at the most suitable level for them, when and how best suit them; in such way, these people will have all the necessary ingredients for choosing the best option when faced with a specific problem (Rodríguez, 2002).

As the knowledge, together with the ability for its best management, has turned into the key factor for the organizations to stand out, it is desirable to determine and develop the support instruments for the generation of such value within the organisations. This situation has been commonly accepted by several authors as (Brooking, 1996) (Davenport & Prusak, 2000) (Huang et al., 1999) (Liebowitz & Beckman, 1998) (Nonaka & Takeuchi, 1995) and (Wiig, 1993) among others. Technological tools should be available for diminishing the communication distance and for providing a common environment where the knowledge might accessible for being stored or shared.

As KM is a very recent discipline, there are few commercial software tools that deal with those aspects necessary for its approach. Most of the tools classified as KM-related are mere tools for managing documents, which is unsuitable for the correct management of the organisations knowledge. Bearing such problem in mind, the present work approaches the establishment

of a KM support software tool based on the own definition of KM and on the existing tools. For achieving this, section 2 presents the market analysis that was performed for studying the existing KM tools, where not only their characteristics were analysed, but also the future needs of the knowledge workers. Following this study, the functionality that a KM support tool should have and the proposal for the best approach to that functionality were identified.

BACKGROUND

The first step for developing a complete KM support tool according to the present and future trade needs is the performance of a study of the existing market. After the initial identification of the characteristics that a KM support tool should have, a posterior work reveals how the studied tools provide support to every one of the previously identified characteristics. Lastly, an evaluation of the obtained results will be performed.

Characteristics to be Considered

The previously mentioned definition of KM was the basis for the identification of the characteristics to be considered, bearing in mind the different aspects that should be supported by the tool.

A KM tool should give support to the following aspects (Andrade et al., 2003a):

- Corporate Memory
 - Yellow Pages
 - Collaboration and Communication mechanisms
1. Corporate Memory
The Corporate Memory compiles the knowledge that exists within an organisation for its workers disposal (Stein, 1995) (Van Heijst et al., 1997). Due to this, to compile and to make the relevant knowledge explicit is equally important than providing the suitable mechanisms for its correct and easy location, as well as recuperation.
 2. Yellow Pages
A KM program should not make the mistake of trying to capture and represent the whole existing knowledge of the organisation, as this attempt would not be feasible; in this sense, the relevant knowledge for the performance of the organisation should be the one to be included. However, not making all the knowledge explicit does not mean that it has to be obviated; for that reason, it is important to determine which knowledge has every individual at the organisation by means of the elaboration of the Yellow Pages. These ones identify and publish additional knowledge sources, human and non-human, that are at the organisation disposal (Davenport & Prusak, 2000).

3. Collaboration and Communication Mechanisms
At the organisations the knowledge is share, as well as distributed, regardless of the automatism, or not, of the process. A knowledge transfer occurs every time that an employee asks a workmate of the adjoining office how to perform a given task. These daily knowledge transfers made the routine of the organisation up but, as they are local and fragmentary, some systems for user collaboration and communication should be therefore established. An adequate KM support tool should include mechanisms that guarantee the efficiency of the collaboration and the communication, regardless of the physical or temporal location of the interlocutors.

Analysed Tools

Once the aspects that a KM support tool should consider have been identified, the following step involves analysing how the current tools consider them.

With such purpose, the main so-named KM support tools that exist currently were analysed, discarding certain tools such as information search engines or simple applications for documents management, as they merely offer partial solutions.

Table 1. Tools analysed

| | Corporate Memory | Yellow Pages | Collaboration and communication mechanisms |
|----------------------------|------------------|--------------|--|
| K-Factory | ✓ | | ✓ |
| Norma K-Factor | ✓ | ✓ | ✓ |
| Hyperwave | ✓ | ✓ | ✓ |
| GTC | ✓ | | ✓ |
| Epicentric | ✓ | ✓ | ✓ |
| Plumtree | ✓ | ✓ | ✓ |
| Intrasuite | ✓ | ✓ | ✓ |
| Coldata | ✓ | ✓ | ✓ |
| Intranets | ✓ | ✓ | ✓ |
| WebSpace | ✓ | | ✓ |
| Knowledge Discovery System | ✓ | ✓ | ✓ |
| Documentum 5 | ✓ | | ✓ |
| Livelink (Opentext) | ✓ | ✓ | ✓ |
| Adenin | ✓ | | ✓ |

The analysis included thirteen tools (Table 1), all of them approaching at least two of the previously mentioned aspects. It should be highlighted that all the tools implement the Corporate Memory as a document warehouse, while the Yellow Pages appear as a telephone directory.

Results Evaluation

After the tools were analysed it was noticed that, for every aspect considered, there are some common elements. Bearing in mind these elements and the current needs, table 2 shows the desirable characteristics that a KM support tool should have.

The conclusions drawn after a deeper study on how the analysed tools approach the desirable characteristics are following presented.

Firstly it was observed that none of the tools classified as KM ones has the necessary structure for best identifying, formalising and sharing the relevant knowledge, as they solely perform documental management complemented, in the best of the cases, by some descriptive fields, the association to a contents tree or by means of links to another related documents. Such fact creates many problems, especially and due to the great data volume, the difficulty for selecting

the adequate knowledge that the user might need at a given moment. Therefore, and as it has been pointed previously, for the best use of the knowledge, it should be somehow structured. The communication supports are also quite important.

The characteristics of a KM support tool should be then necessarily defined, together with a guide for approaching them.

RECOMMENDED FEATURES

The approach to every one of the detected characteristics should be initiated as soon as the functionality that a support tool for the explicit management of the corporate knowledge might have been determined.

1. Corporate Memory: the organisation knowledge has to be physically stored somehow by means of a Corporate Memory for being adequately shared. A Corporate Memory is an explicit, independent and persistent knowledge representation (Stein, 1995) (Van Heijst et al., 1997) that can be considered as a knowledge repository from the individuals that work at a given organisation. The Corporate Memory should include the following aspects:

Table 2. Desirable characteristics of a KM support tool

| Aspect | Desirable characteristic | |
|--|----------------------------|---|
| Corporate Memory | | Knowledge formalisation |
| | | Knowledge Incorporation |
| | | New knowledge notification |
| | | Search |
| Yellow Pages | | Experts search |
| | | Integration |
| Collaboration and communication mechanisms | Asynchronous communication | Workgroup |
| | | Workflow |
| | | Management of time, tasks and resources |
| | | E-mail |
| | Synchronous communication | Forum |
| | | Suggestion box |
| | | Notice board |
| | | Chat |
| | | Electronic board |
| | | Audio-conference |
| | | Video-conference |

- 1.1. Knowledge formalisation. Before being included into the Corporate Memory, the knowledge has to be formalised by means of the determination of, not only the relevant knowledge, but also the attributes that describe it. When performing this formalisation it should be born in mind that there are two types of knowledge; on one hand, the Corporate Memory must include the knowledge needed to describe the operations for performing an organisational task. On the other side, it is necessary to capture the knowledge that has been acquired by the individuals after their experience and life time. This markedly heuristic knowledge is known as *Learned Lessons*: positive as well as negative experiences that can be used for improving the future performance of the organisation (Van Heijst, 1997), and therefore refining its current knowledge.
 - a. Organisational knowledge (Andrade et al., 2003b). A KM system should consider different types of knowledge when structuring the relevant knowledge associated to the operations that exist at the organisation:
 - Strategic or control knowledge: it indicates, not only what to do, but also why, where and when. For that reason, the constituents of the functional disintegration of every operation should be identified.
 - Tactical: it specifies how and under what circumstances the tasks are done. This type of knowledge is associated with the execution process of every last-level strategic step.
 - b. Learned lessons. It is related to the experience and the knowledge that the individuals have with regards to their task. It provides the person who possesses it with the ability for refining both, the processes that follows at work and the already existing knowledge, in order to be more efficient. Whereas it's appropriate to create systems of learned lessons (Weber, 2001) in order to save this type of knowledge.
- 1.2. Incorporation mechanisms. The knowledge can be incorporated in an active or passive way (Andrade et al., 2003c). The active incorporation is based on the existence of a KM group in charge of looking after the quality of the knowledge that is going to be incorporated. This guarantees the quality of the knowledge included into the Corporate Memory but it also takes human resources up. Differently from the previous way, at the passive incorporation does not exist any group for quality evaluation, as the own individual ready to share knowledge and experience will be responsible for evaluating that the proposal fulfils the minimum requirements of quality and relevancy. The main advantage of the second alternative is that it does not take additional resources up. Bearing in mind the previous considerations, the active knowledge incorporation is preferred whenever it might be possible, as in such way the quality and the relevancy of the knowledge will be guaranteed.
- 1.3. Notification mechanisms. All the members of the organisation should be informed when a new knowledge is incorporated as this enables the refinement of their knowledge. The step previous to the notification is the definition of the group of people that will be informed of the new appearance of a knowledge item. There are two alternatives (García et al., 2003): subscription, where every individual at the organisation might take out a subscription to certain preferred specific issues, and spreading, where the notification messages reach the workers without previous request. At the spreading, the messages can be sent to all the members of the organisation, but this is not advisable as the receptor would be not able of discern which ones of the vast amount of messages received might be interesting for him/her. Other spreading possibility would rely on an individual or a group that would be in charge of determining the addressees for every given message; this last option is quite convenient for the members of the organisation but it takes up a vast amount of resources that have to contain themselves

a lot of information regarding the interests of every one of the members.

1.4. Localisation mechanisms. The tool should be provided with some search mechanism in order to achieve the maximum possible profit from the captured and incorporated knowledge (Tiwana, 2000). It is necessary to reach an agreement between efficiency and functionality, as enough search options should be available without increasing the system complexity. For this reason, the following search mechanisms are suggested:

- Hierarchy search: this search catalogues the knowledge into a fixed hierarchy, in such way that the user might move through a group of links for refining the search performed.
- Attribute search: is based on the specification of terms in which the user is interested, resulting into some knowledge elements that might content those terms. This type of search provides more general results than the previous one.

2. Yellow Pages: a KM system should not try to capture and assimilate the whole of the knowledge that exists at the organisation as it would not be feasible. Therefore, the Yellow Pages are used for including, not only the systems that store knowledge, but also the individuals that have additional knowledge. Their elaboration is performed after determining the knowledge possessed by every individual at the organisation or by any other non human agents.

3. Collaboration and communication mechanisms: at the organisations, the knowledge is shared and distributed regardless the process might be automated or not. The technology helps the interchange of knowledge and ideas among the members of the organisation, as it enables bringing the best possible knowledge within reach of the individual who requires it. The collaboration and communication mechanisms detected are the following:

3.1 Asynchronous communication. Does not require the connection between the ends of the communication at the same time.

- E-mail. The electronic messenger enables the interchange of text and/or

any other type of document among two or several users

- Forum. It consists of a Web page where the participants leave questions that do not have to be answered at that very moment. Other participants leave the answers which, together with the questions, can be seen by anyone entering the forum at any moment.
- Suggestion box. It enables sending suggestions or comments of any relevant aspect of the organisation to the adequate person or department.
- Notice board. It is a common space where the members of the organisation can publish some announcements appropriate for the public interest.

3.2 Synchronous communication. This type of interactive technology is based on real-time communications. Some of the most important systems are the following:

- Chat. It implies the communication among several people through the computer, as all the people connected can follow the communication, express an opinion, contribute ideas, make or answer questions when they decide.
- Electronic board. It provides the members of the organisation with a shared space for improving the interchange the ideas where everybody draws or writes.
- Audio conference. Two or more users can use real-time voice communication.
- Video conference. Two or more users can use real-time image communication.

FUTURE TRENDS

As it has been mentioned before, there is not a current KM tool that might cover adequately the organisational needs. This problem has been approached in the present work by trying to determine the functionality that any of these tools should incorporate. This is a first step that should be complemented with subsequent works, as it

is necessary to go deeper and determine better how to approach and implement the specified aspects.

CONCLUSION

The knowledge, either for its management or not, is transmitted within the organisations, although its existence does not imply its adequate use. There is a vast amount of knowledge where access is extremely difficult; this means that there are items from where no return is being achieved and that they are lost into the organisation. The KM represents the effort for capturing and getting benefits from the collective experience of the organisation by means of turning it accessible to any of its members. However, it could be stated that not a current tool is able to efficiently perform this task as, although there exist the so-named KM tools, they merely store documents and none of them performs the structuration of the relevant knowledge for its best use.

In order to palliate such problems, the present work proposes an approach based on a market research. It is as well based on the KM definition that indicates how to approach and defines the characteristics that a tool should have for working as facilitator of an adequate and explicit Knowledge Management.

KEY TERMS

Communication & Collaboration Tool: Systems that enable collaboration and communication among members of an organisation (i.e. chat applications, whiteboards).

Document Management: It is the computerised management of electronic, as well as paper-based documents.

Institutional Memory: It is the physical storage of the knowledge entered in an organization.

Knowledge: Pragmatic level of information that provides the capability of dealing with a problem or making a decision.

Knowledge Management: Discipline that intends to provide, at its most suitable level, the accurate information and knowledge for the right people, whenever they may needed and at their best convenience.

Knowledge Management Tool: Organisational system that connects people with the information and communication technologies, with the purpose of improving the share and distribution processes of the organisational knowledge.

Lesson Learned: Specific experience, positive or negative, of a certain domain. It is obtained into a practical context and can be used during future activities of similar contexts.

Yellow Page: It storages information about a human or non-human source that has additional and/or specialized knowledge about a particular subject.

Knowledge-Based Systems

K

INTRODUCTION

The tools of artificial intelligence (AI) can be divided into two broad types: knowledge-based systems (KBSs) and computational intelligence (CI). KBSs use explicit representations of knowledge in the form of words and symbols. This explicit representation makes the knowledge more easily read and understood by a human than the numerically derived implicit models in computational intelligence.

KBSs include techniques such as rule-based, model-based, and case-based reasoning. They were among the first forms of investigation into AI and remain a major theme. Early research focused on specialist applications in areas such as chemistry, medicine, and computer hardware. These early successes generated great optimism in AI, but more broad-based representations of human intelligence have remained difficult to achieve (Hopgood, 2003; Hopgood, 2005).

BACKGROUND

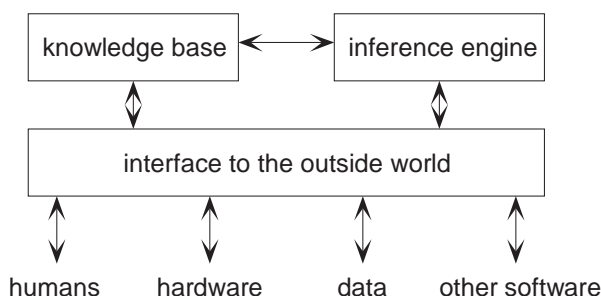

The principal difference between a knowledge-based system and a conventional program lies in its structure. In a conventional program, domain knowledge is intimately intertwined with software for controlling the

application of that knowledge. In a knowledge-based system, the two roles are explicitly separated. In the simplest case there are two modules: the knowledge module is called the knowledge base and the control module is called the inference engine. Some interface capabilities are also required for a practical system, as shown in Figure 1.

Within the knowledge base, the programmer expresses information about the problem to be solved. Often this information is declarative, i.e. the programmer states some facts, rules, or relationships without having to be concerned with the detail of how and when that information should be applied. These latter details are determined by the inference engine, which uses the knowledge base as a conventional program uses a data file. A KBS is analogous to the human brain, whose control processes are approximately unchanging in their nature, like the inference engine, even though individual behavior is continually modified by new knowledge and experience, like updating the knowledge base.

As the knowledge is represented explicitly in the knowledge base, rather than implicitly within the structure of a program, it can be entered and updated with relative ease by domain experts who may not have any programming expertise. A knowledge engineer is someone who provides a bridge between the domain

Figure 1. The main components of a knowledge-based system

expertise and the computer implementation. The knowledge engineer may make use of meta-knowledge, i.e. knowledge about knowledge, to ensure an efficient implementation.

Traditional knowledge engineering is based on models of human concepts. However, it has recently been argued that animals and pre-linguistic children operate effectively in a complex world without necessarily using concepts. Moss (2007) has demonstrated that agents using non-conceptual reasoning can outperform stimulus–response agents in a grid-world test bed. These results may justify the building of non-conceptual models before moving on to conceptual ones.

TYPES OF KNOWLEDGE-BASED SYSTEM

Expert Systems

Expert systems are a type of knowledge-based system designed to embody expertise in a particular specialized domain such as diagnosing faulty equipment (Yanga, 2005). An expert system is intended to act like a human expert who can be consulted on a range of problems within his or her domain of expertise. Typically, the user of an expert system will enter into a dialogue in which he or she describes the problem – such as the symptoms of a fault – and the expert system offers advice, suggestions, or recommendations. It is often proposed that an expert system must offer certain capabilities that mirror those of a human consultant. In particular, it is often stated that an expert system must be capable of justifying its current line of inquiry and explaining its reasoning in arriving at a conclusion. This functionality can be integrated into the inference engine (Figure 1).

Rule-Based Systems

Rules are one of the most straightforward means of representing knowledge in a KBS. The simplest type of rule is called a production rule and takes the form:

if <condition> then <conclusion>

An example production rule concerning a boiler system might be:

/* rule1 */

if valve is open and flow is high then steam is escaping

Part of the attraction of using production rules is that they can often be written in a form that closely resembles natural language, as opposed to a computer language. The facts in a KBS for boiler monitoring might include:

/* fact1 */

valve is open

/* fact2 */

flow is high

One or more given facts may satisfy the condition of a rule, resulting in the generation of a new fact, known as a derived fact. For example, by applying rule1 to fact1 and fact2, fact3 can be derived:

/* fact3 */

steam is escaping

The derived fact may satisfy the condition of another rule, such as:

/* rule2 */

if steam is escaping or valve is stuck then outlet is blocked

This, in turn, may lead to the generation of a new derived fact or an action. Rule1 and rule2 are inter-dependent, since the conclusion of one can satisfy the condition of the other. The inter-dependencies amongst the rules define a network, as shown in Figure 2, known as an inference network.

It is the job of the inference engine to traverse the inference network to reach a conclusion. Two important types of inference engine can be distinguished: forward-chaining and backward-chaining, also known as data-driven and goal-driven, respectively. A KBS working in data-driven mode takes the available information, i.e. the given facts, and generates as many derived facts as it can. In goal-driven mode, evidence is sought to support a particular goal or proposition.

The data-driven (forward chaining) approach might typically be used for problems of interpretation, where the aim is to find out whatever the system can infer about some data. The goal-driven (backward chaining)

Figure 2. An inference network for a boiler system

approach is appropriate when a more tightly focused solution is required, such as the generation of a plan for a particular goal. In the example of a boiler monitoring system, forward chaining would lead to the reporting of any recognised problems. In contrast, backward chaining might be used to diagnose a specific mode of failure by linking a logical sequence of inferences, disregarding unrelated observations.

The rules that make up the inference network in Figure 2 are used to link cause and effect:

if <cause> then <effect>

Using the inference network, an inference can be drawn that if the valve is open and the flow rate is high (the causes) then steam is escaping (the effect). This is the process of *deduction*. Many problems, such as diagnosis, involve reasoning in the reverse direction, i.e. the user wants to ascertain a cause, given an effect. This is *abduction*. Given the observation that steam is escaping, abduction can be used to infer that valve is open and the flow rate is high. However, this is only a valid conclusion if the inference network shows *all* of the circumstances in which steam may escape. This is the closed-world assumption.

If many examples of cause and effect are available, the rule (or inference network) that links them can be inferred. For instance, if every boiler blockage ever seen was accompanied by steam escaping and a stuck valve, then rule2 above might be inferred from those examples. Inferring a rule from a set of example cases of cause and effect is termed *induction*.

Hopgood (2001) summarizes deduction, abduction, and induction as follows:

- deduction: cause + rule \Rightarrow effect
- abduction: effect + rule \Rightarrow cause
- induction: cause + effect \Rightarrow rule

Logic Programming

Logic programming describes the use of logic to establish the truth, or otherwise, of a proposition. It is, therefore, an underlying principle for rule-based systems. Although various forms of logic programming have been explored, the most commonly used one is the Prolog language (Bramer, 2005), which embodies the features of backward chaining, pattern matching, and list manipulation.

The Prolog language can be programmed declaratively, although an appreciation of the procedural behavior of the language is needed in order to program it effectively. Prolog is suited to symbolic problems, particularly logical problems involving relationships between items. It is also suitable for tasks that involve data lookup and retrieval, as pattern-matching is fundamental to the functionality of the language.

Symbolic Computation

A knowledge base may contain a mixture of numbers, letters, words, punctuation, and complete sentences. These symbols need to be recognised and processed by the inference engine. Lists are a particularly useful

data structure for symbolic computation, and they are integral to the AI languages Lisp and Prolog. Lists allow words, numbers, and symbols to be combined in a wide variety of ways. A list in the Prolog language might look like this:

```
[animal, [cat, dog], vegetable, mineral]
```

where this example includes a nested list, i.e. a list within a list. In order to process lists or similar structures, the technique of pattern matching is used. For example, the above list in Prolog could match to the list

```
[animal, [_ , X], vegetable, Y]
```

where the variables X and Y would be assigned values of dog and mineral respectively. This pattern matching capability is the basis of an inference engine's ability to process rules, facts and evolving knowledge.

Uncertainty

The examples considered so far have all dealt with unambiguous facts and rules, leading to clear conclusions. In real life, the situation can be complicated by three forms of uncertainty:

Uncertainty in the Rule Itself

For example, rule 1 (above) stated that an open valve and high flow rate lead to an escape of steam. However, if the boiler has entered an unforeseen mode, it made be that these conditions do not lead to an escape of steam. The rule ought really to state that an open valve and high flow rate will *probably* lead to an escape of steam.

Uncertainty in the Evidence

There are two possible reasons why the evidence upon which the rule is based may be uncertain. First, the evidence may come from a source that is not totally reliable. For example, in rule 1 there may be an element of doubt whether the flow rate is high, as this information relies upon a meter of unspecified reliability. Second, the evidence itself may have been derived by a rule whose conclusion was probable rather than certain.

Use of Vague Language

Rule 1, above, is based around the notion of a "high" flow rate. There is uncertainty over whether "high" means a flow rate of the order of $1\text{cm}^3\text{s}^{-1}$ or $1\text{m}^3\text{s}^{-1}$.

Two popular techniques for handling the first two sources of uncertainty are Bayesian updating and certainty theory (Hopgood, 2001). Bayesian updating has a rigorous derivation based upon probability theory, but its underlying assumptions, e.g., the statistical independence of multiple pieces of evidence, may not be true in practical situations. Certainty theory does not have a rigorous mathematical basis, but has been devised as a practical and pragmatic way of overcoming some of the limitations of Bayesian updating. It was first used in the classic MYCIN system for diagnosing infectious diseases (Buchanan, 1984). Other approaches are reviewed in (Hopgood, 2001), where it is also proposed that a practical non-mathematical approach is to treat rule conclusions as hypotheses that can be confirmed or refuted by the actions of other rules. Possibility theory, or fuzzy logic, allows the third form of uncertainty, i.e. vague language, to be used in a precise manner.

Decision Support and Analysis

Decision support and analysis (DSA) and decision support systems (DSSs) describe a broad category of systems that involve generating alternatives and selecting among them. Web-based DSA, which uses external information sources, is becoming increasingly important. Decision support systems that use artificial intelligence techniques are sometimes referred to as intelligent DSSs.

One clearly identifiable family of intelligent DSS is expert systems, described above. An expert system may contain a mixture of simple rules based on experience and observation, known as heuristic or shallow rules, and more fundamental or deep rules. For example, an expert system for diagnosing car breakdowns may contain a heuristic that suggests checking the battery if the car will not start. In contrast, the expert system might also contain deep rules, such as Kirchhoff's laws, which apply to any electrical circuit and could be used in association with other rules and observations to diagnose any electrical circuit. Heuristics can often

provide a useful shortcut to a solution, but lack the adaptability of deep knowledge.

Building and maintaining a reliable set of cause–effect pairs in the form of rules can be a huge task. The principle of model-based reasoning (MBR) is that, rather than storing a huge collection of symptom–cause pairs in the form of rules, these pairs can be *generated* by applying underlying principles to the model. The model may describe any kind of system, including systems that are physical (Fenton, 2001), software-based (Mateis, 2000), medical (Montani, 2003), legal (Bruninghaus, 2003), and behavioral (De Koning, 2000). Models of physical systems are made up of fundamental components such as tubes, wires, batteries, and valves. As each of these components performs a fairly simple role, it also has a simple failure mode. Given a model of how these components operate and interact to form a device, faults can be diagnosed by determining the effects of local malfunctions on the overall device.

Case-based reasoning (CBR) also has a major role in DSA. A characteristic of human intelligence is the ability to recall previous experience whenever a similar problem arises. This is the essence of case-based reasoning (CBR), in which new problems are solved by adapting previous solutions to old problems (Bergmann, 2003).

Consider the example of diagnosing a broken-down car. If an expert system has made a successful diagnosis of the breakdown, given a set of symptoms, it can file away this information for future use. If the expert system is subsequently presented with details of another broken-down car of exactly the same type, displaying exactly the same symptoms in exactly the same circumstances, then the diagnosis can be completed simply by recalling the previous solution. However, a full description of the symptoms and the environment would need to be very detailed, and it is unlikely to be reproduced exactly. What is needed is the ability to identify a previous case, the solution of which can be reused or modified to reflect the slightly altered circumstances, and then saved for future use. Such an approach is a good model of human reasoning. Indeed case-based reasoning is often used in a semi-automated manner, where a human can intervene at any stage in the cycle.

FUTURE TRENDS

While large corporate knowledge-based systems remain important, small embedded intelligent systems have also started to appear in the home and workplace. Examples include washing machines that incorporate knowledge-based control and wizards for personal computer management. By being embedded in their environment, such systems are less reliant on human data input than traditional expert systems, and often make decisions entirely based on sensor data.

If AI is to become more widely situated into everyday environments, it needs to become smaller, cheaper, and more reliable. The next key stage in the development of AI is likely to be a move towards *embedded* AI, i.e. intelligent systems that are embedded in machines, devices, and appliances. The work of Choy (2003) is significant in this respect, as it demonstrates that the DARBS blackboard system can be ported to a compact platform of parallel low-cost processors.

In addition to being distributed in their applications, intelligent systems are also becoming distributed in their method of implementation. Complex problems can be divided into subtasks that can be allocated to specialized collaborative agents, bringing together the best features of knowledge-based and computation intelligence approaches (Li, 2003). As the collaborating agents need not necessarily reside on the same computer, an intelligent system can be both distributed and hybridized (Choy, 2004). Paradoxically, there is also a sense in which intelligent systems are becoming more integrated, as software agents share access to a single definitive copy of data or knowledge, accessible via the web.

CONCLUSION

As with any technique, knowledge-based systems are not suitable for all types of problems. Each problem calls for the most appropriate tool, but knowledge-based systems can be used for many problems that would be impracticable by other means. They have been particularly successful in narrow specialist domains. Building an intelligent system that can make sensible decisions about unfamiliar situations in everyday, non-specialist domains remains a severe challenge.

This development will require progress in simulating behaviors that humans take for granted – specifically perception, recognition, language, common sense, and adaptability. To build an intelligent system that spans the breadth of human capabilities is likely to require a hybrid approach using a combination of artificial intelligence techniques.

KEY TERMS

Backward Chaining: Rules are applied through depth-first search of the rule base to establish a goal. If a line of reasoning fails, the inference engine must backtrack and search a new branch of the search tree. This process is repeated until the goal is established or all branches have been explored.

Case-Based Reasoning: Solving new problems by adapting solutions that were previously used to solve old problem.

Closed-World Assumption: The assumption that all knowledge about a domain is contained in the knowledge base. Anything that is not true according to the knowledge base is assumed to be false.

Deep Knowledge: Fundamental knowledge with general applicability, such as the laws of physics, which can be used in conjunction with other deep knowledge to link evidence and conclusions.

Forward Chaining: Rules are applied iteratively whenever their conditions are satisfied, subject to a selection mechanism known as conflict resolution when the conditions of multiple rules are satisfied.

Heuristic or Shallow Knowledge: Knowledge, usually in the form of a rule, that links evidence and conclusions in a limited domain. Heuristics are based on observation and experience, without an underlying derivation or understanding.

Inference Network: The linkages between a set of conditions and conclusions.

Knowledge-Based System: System in which the *knowledge base* is explicitly separated from the *inference engine* that applies the knowledge.

Model-Based Reasoning: The knowledge base comprises a model of the problem area, constructed from component parts. The inference engine reasons about the real world by exploring behaviors of the model.

Production Rule: A rule of the form if <condition> then <conclusion>.

INTRODUCTION

In the analysis of a temporal process, Kohonen maps may be used together with time-series (TS) algorithms. Previous research aimed at combining Kohonen algorithms and Markov switching models in order to suggest a periodization of the international bimetalism in the 19th century (Boyer-Xambeu, Deleplace, Gaubert, Gillard and Olteanu, 2006). This research was based on an economic study of the international monetary system ruling at this time in Europe, which combined three monetary zones: a gold-standard one, centred in London, a bimetallic one, centred in Paris, and a silver-standard one, centred in Hamburg (Boyer-Xambeu, Deleplace and Gillard, 2006). The three major financial centres of that system (London, Paris, and Hamburg, hence the label LPH used hereafter) were linked through arbitrage operations between markets for gold and silver and markets for foreign exchange located in those centres. Since two metals, gold and silver, acted as monetary standards in that system, it worked as an international bimetalism. Its growing integration during half a century (from 1821 to 1873) was reflected in the convergence of the observed levels of the relative price of gold to silver in London, Paris, and Hamburg. However, this integration process was subject to various changes, which can be understood as exogenous shocks disturbing that process.

One such shock is vastly documented in the literature: the discovery of new gold mines in the United States and Australia, which led to a sudden decline in 1850 of the gold-silver price over all the markets in the world. This decline was not of the same magnitude everywhere, and therefore the spread between the London, Paris, and Hamburg gold-silver prices increased, stopping for a time the integration process of the system. This is what we will call a breaking in that process. The present paper aims at locating the major breakings occurring during the period of international bimetalism; a historical study could link them to special events, which operated as exogenous shocks on that system. The indicator of integration used is the spread between the highest and the lowest among the London, Paris, and Hamburg gold-silver prices.

Three algorithms are combined to study this integration: a periodization obtained with the SOM algorithm is confronted to the estimation of a two-regime Markov switching model, in order to give an interpretation of the changes of regime; at the same time change-points are identified over the whole period providing a more precise interpretation of these varying types of regulation.

Section 2 summarizes the results obtained with the SOM algorithm to differentiate the sub-periods obtained using the whole available data.

Section 3 presents the kind of model used and the results of its estimation using the new indicator, the

spread computed at each period of quotation between the three relative prices of gold in silver. The sub-periods are confronted to the two regimes obtained and some evidence of a relation between the regime and the volatility of the spread is presented.

Section 4 presents the technique used to identify change-points in the temporal process and some strong results of breaks in mean and in variance of the spread are obtained. They are interpreted in terms of monetary history as, for some of them, they are quite new in the literature of this domain.

Some further directions of research are indicated in conclusion.

THE SUB-PERIODS OBTAINED WITH A SOM ALGORITHM¹

The Data

The relative prices of gold in silver are computed from the price of each metal observed, twice a week, in each of the three financial places, Paris, London and Hamburg (respectively, *poa*, *lgs*, and *hoa*), from the beginning of 1821 until the end of 1860. The same type of data is available for the exchange rates (Pound in Francs, Pound in Marks, Mark in Francs: respectively, *lpv*, *hlv*, and *phv*).

An observation is a set of twelve values, two quotations (Tuesday and Friday) for each of the six variables.

A computed variable has been added to emphasize the relation between the relative price of metals in Hamburg and the average level in Paris and London of this value (*hpl*).

Most of the time the quotations show rather small differences within a given week, but periods with important troubles, Paris in the late 1840s for instance, may be well separated from the more classical ones.

After the Kohonen classification using a grid of 25 nodes, a hierarchical ascending classification is used to produce a small number of macro classes, in this case 6 macro classes, corresponding to the main sub-periods. This latter classification is constructed with the code vectors obtained from the first process².

Characteristics of the Macro-Classes

Large sequences of contiguous weeks are grouped in the macro-classes, however a few years are fragmented in short periods situated in different classes

- Class 1 is constituted of 3 groups of years 1829-30, 1834-38, 1848-49 and a lot of fragments of other years
- Class 2 is more simple to describe with 3 intervals 1832-33, 1842-43 and 1846-47 and some sparse weeks from the 1830s.

They represent a central position contrasting to the well identified other classes:

- Class 3: 2 sets constituted of years 1824-25 and 1827-28, with almost no missing weeks in these intervals, indicating that this sub-period is very homogeneous
- Class 4: the end of year 1853 and the whole period 1854-60; again only a small number of weeks are missing for this continuous sub-period of more than seven years
- Class 5: 1821-24 and 1826-beginning 1827 plus small parts of 1830 and 1832
- Class 6: two sets 1839-41 and 1851-53

The means of the variables used to obtain the classification can be represented to illustrate the great differences appearing between the sub-periods. Changing hierarchies between the relative prices are the characteristic identifying the four last macro-classes.

Rearranging the various classes according to calendar time allows to distinguish between three sub-periods: a) the 1820s (classes 5 and 3, covering 1821 to 1828); b) the 1830s and 1840s (classes 1 and 2, covering 1829 to 1849); c) the 1850s (classes 6 and 4, covering 1851 to 1860).

Only the years 1839-41 resist to that rearrangement, since they belong to class 6, while they should appear in classes 1 and 2 relative to the 1830s and 1840s; some explanation will be suggested in the last section.

Fig. 1. exhibits two contrasted situations, where the gold-silver price is respectively low (class 4) and high (class 5) in all the three financial centres. Fig. 2. confirms that opposition, since the two classes are also

Figure 1. Gold-silver price and the 6 macro-classes

Figure 2. Exchange rates and the 6 macro-classes

sharply contrasted by the levels of the exchange rates. Years 1821-23 and 1826 (class 5) are marked by a low mark/franc exchange rate and high gold-silver prices, the Hamburg one being higher than the Paris one; years 1854-60 (class 4) are marked by a high mark/franc exchange rate and low gold-silver prices, the Hamburg one being below the Paris one.

These remarks, which also apply respectively to the rest of the 1820s (class 3) and to the rest of the 1850s (class 6) are consistent with historical analysis: while the Hamburg mark was always anchored to silver, the French franc was during the 1820s and 1850s anchored to gold (in contrast with the 1830s and 1840s when it was anchored to silver); it is then normal that the mark

depreciated against the franc when silver depreciated against gold, and more in Hamburg than in Paris (as in class 5 and 3), and that the mark appreciated against the franc when silver appreciated against gold, and more in Hamburg than in Paris (as in class 4 and 6).

A MODEL FOR THE SPREAD BETWEEN THE HIGHEST AND THE LOWEST GOLD-SILVER PRICE

An Autoregressive Markov Switching Model

The key assumption is that the time series to be modeled follow a different pattern or a different model according to some unobserved, finite valued process. Usually, the unobserved process is a Markov chain whose states are called “regimes”, while the observed series follows a linear autoregressive model whose coefficients depend on the current regime.

Let us put this in a mathematical language. Suppose that $(y_t)_{t \in \mathbb{Z}}$ is the observed time series and that the unobserved process $(x_t)_{t \in \mathbb{Z}}$ is a two-states Markov chain with transition matrix

$$A = \begin{pmatrix} p & 1-q \\ 1-p & q \end{pmatrix}, \text{ where } p, q \in]0,1[\quad (1)$$

Then, assuming that y_t depends on the first l lags of time, we have the following equation of the model:

$$y_t = a_0^{x_t} + a_1^{x_t} y_{t-1} + \dots + a_l^{x_t} y_{t-l} + \sigma^{x_t} \varepsilon_t \quad (2)$$

where $a_i^{x_t} \in \{a_i^1, a_i^2\} \in \mathbb{R}^2$ for every $i \in \{0, 1, \dots, l\}$, $\sigma^{x_t} \in \{\sigma^1, \sigma^2\} \in (\mathbb{R}_+^*)^2$ and ε_t is a standard Gaussian noise.

The parameters of the model are then

$$\{a_0^1, a_1^1, \dots, a_l^1, a_0^2, a_1^2, \dots, a_l^2, \sigma^1, \sigma^2, p, q\}$$

and they are usually estimated by maximizing the log-likelihood function via an EM (Expectation – Maximization) algorithm³.

Our characteristic of interest will be the “a posteriori” computed conditional probabilities of belonging to the first or to the second regime. Indeed, as our goal is to derive a periodization of the international bimetallism, the “a posteriori” computed states of the unobserved Markov chain will provide a natural one.

Although the results obtained with a switching Markov model are usually satisfying in terms of prediction and the periodizations are interesting and easily interpretable, a difficulty remains: how does one choose the number of regimes? In the absence of a complete theoretical answer, the criteria for selecting the “right” number of regimes are quite subjective from a statistical point of view⁴.

The Results

In this paper we use a two-regime model to represent the spread computed with the gold-silver prices observed at each period on the three places. The transition matrix indicates good properties of stability:

$$\begin{pmatrix} 0.844298 & 0.253357 \\ 0.155702 & 0.746643 \end{pmatrix}$$

and no three regime model was found with an acceptable stability.

The first regime is a multilayer perceptron with one hidden layer, the second one is a simple linear model with one lag. Using the probabilities computed for each regime at each period, it may be interesting to study

Table 1. Regime 1 and volatility of spread

| Sub-periods | Number of obs. | % regime 1 | Standard deviation of spread |
|-------------|----------------|------------|------------------------------|
| 1 | 483 | 0.733 | 0.053 |
| 2 | 335 | 0.627 | 0.061 |
| 3 | 191 | 0.445 | 0.075 |
| 4 | 376 | 0.816 | 0.044 |
| 5 | 303 | 0.625 | 0.050 |
| 6 | 390 | 0.723 | 0.049 |

the six sub-periods obtained and to observe the switch between the regimes along these periods of time.

Most of the time the regime 1 explains the spread (about 70% of the whole period) but important differences are to be noted between the sub-periods:

Classes 3 and 4 clearly contrast with, respectively, the highest and the lowest volatility of spread as they are ruled by, respectively, regime 2 and regime 1 models.

As will be explained later, further investigations have to be made with a more complex model and using a more adapted indicator of the arbitrages ruling the markets.

IDENTIFICATION OF CHANGE-POINTS: A GLOBAL VISION OF THE BIMETALLIST SYSTEM OF PAYMENTS

Elements About the Technique⁵

A different approach to model changes of regime in a time-series is to detect change-points or breaks. Here, the main assumption is that the whole series is observed and change-points are computed “a posteriori”. Thus, this approach has not a predictive goal, but it is rather aimed at explaining the series by a piecewise stationary process which seems to be well adapted to our problem.

Mathematically, the model can be written as follows: let us consider the observed m -dimensional series $y_t = \{y_{1,t}, \dots, y_{m,t}\}^T$, $t = 1, \dots, T$ and suppose that it is abruptly

changed. The changes, whose number and configuration are unknown, occur in the marginal distribution and may be in mean, in variance or in both mean and variance. We assume that there exists an integer K^* and a sequence of change-points $\tau^* = \{\tau_1^*, \dots, \tau_{K^*}^*\}$ with $\tau_0^* = 0 < \tau_1^* < \dots < \tau_{K^*-1}^* < \tau_{K^*}^* = T$ such that $(\mu_k, \sum_k) \neq (\mu_{k+1}, \sum_{k+1})$ where $\mu_k = E(Y_t)$ and $\sum_k = Cov(Y_t) = E(Y_t - E(Y_t))(Y_t - E(Y_t))^T$, $\tau_{k-1}^* + 1 \leq t \leq \tau_k^*$.

The numbers of changes as well as their configuration are computed by minimizing a penalized contrast function. Details on the algorithms for computing the change-points configuration τ^* can be found in Lavielle and Teyssi re (2006)⁶.

Some Results and Interpretation

Applying this technique to the spread gave 7 change-points in mean and 4 in mean and variance.

Fig. 3 summarizes the spread, the four change-points (the first 4 green lines in chronological order) obtained in mean and variance, and the 2 last change-points in mean which correspond to a major break in the level of the gold-silver price, observed simultaneously on the three places and correspond to the great change in production of gold in United States.

A closer look at the spread between the highest and the lowest among the London, Hamburg and Paris gold-silver prices draws attention upon three episodes, each of them beginning with a break which sharply increases the spread and ends with another breaking which sharply narrows it (green vertical lines on Fig. 3). These episodes have in common to be linked to

Figure 3. Spread, change-points and probability of regime 1

shocks affecting the integration process of the LPH system, although the shocks may have been asymmetrical (only one or two of the financial centres being initially hit) or symmetrical (the three of them being simultaneously hit).

The first episode runs from the 21st week of 1824 till the 41st week of 1825. The sharp initial increase in the spread may be explained by two opposite movements in London and Hamburg: on one side, heavy speculation in South-American bonds and Indian cotton fuelled in London the demand for foreign payments in silver, which resulted in a great increase in the price of silver and a corresponding decline in the gold-silver price; on the other side, the price of gold rose in Hamburg while the price of silver remained constant, sparking the huge spread between the highest (Hamburg) and the lowest (London) gold-silver prices. More than one year later, the opposite movements took place: the price of gold plunged in Hamburg, while the price of silver remained at its height in London, under the influence of continuing speculation (which would end up in the famous banking crisis of December 1825); consequently the spread abruptly narrowed, this event being reflected by the breaking of the 41st week of 1825.

The second episode runs from the 45th week of 1839 till the 13th week of 1843. It started with the attempt of Prussia to unify the numerous German-speaking independent states in a common monetary zone, on a silver standard. Since the Bank of Hamburg maintained the price of silver fixed, that pressure on silver led to a drop in the Hamburg price of gold, and consequently in its gold-silver price, at a time when it was more or less stabilized in Paris. The spread between the highest (Paris) and the lowest (Hamburg) gold-silver price suddenly was enlarged, and during more than three years remained at a level significantly higher than during the 14 preceding years. This episode ended with the breaking of the 13th week of 1843, when, this shock having been absorbed, the gold-silver price in Hamburg went back in line with the price in the two other financial centres.

The third episode runs from the 46th week of 1850 till the 41st week of 1854. The shock was then symmetrical: London, Paris and Hamburg were hit by the pouring of gold following the discovery of Californian mines, and the sudden downward pressure on the world price of that metal. It took four years to absorb this

enormous shock, as reflected by the breaking of the 41st week of 1854.

CONCLUSION

In the three cases, the integration process of the LPH system, shown by the downward trend of the spread over half a century, was jeopardized by a shock: a speculative one in 1824, an institutional one in 1839, a technological one in 1850. But the effects of these shocks were absorbed after some time, thanks to active arbitrage operations between the three financial centres of the system. Generally, that arbitrage did not imply the barter of gold for silver but the coupling of a foreign exchange operation (on bills of exchange) with the transport of one metal only.

As a consequence, it would be appropriate in a further study to locate the breakings of another indicator of integration: the spread between a representative “national” gold-silver price and an arbitrated international gold-silver price taking into account the foreign exchange rates. At the same time it would be interesting to go further with the Markov switching model, trying more complete specifications.

KEY TERMS

Change-Point: Instant of time where the basic parameters of time series change (in mean and/or in variance); the series may be considered as a piecewise stationary process between two change-points

Gold-Silver Price: Ratio of the market price of gold to the market price of silver in one place. The stability of that ratio through time and the convergence of its levels in the various places constituting the international bimetallism (see that definition) are tests of the integration of that system.

International Arbitrage: Activity of traders in gold and silver and in foreign exchange, which consisted in comparing their prices in different places, and in moving the precious metals and the bills of exchange accordingly, in order to make a profit. Arbitrage and monetary rules were the two factors explaining the working of international bimetallism (see that definition).

International Bimetallism: An international monetary system (see that definition) which worked from 1821 to 1873. It was based on gold and silver acting as monetary standards, either together in the same country (like France) or separately in different countries (gold in England, silver in German and Northern states). The integration of that system was reflected in the stability and the convergence of the observed levels of the relative price of gold to silver (see that definition) in London, Paris, and Hamburg.

International Monetary System: A system linking the currencies of various countries, which ensures

the stability of the exchange rates between them. Its working depends on the monetary rules adopted in each country and on international arbitrage (see that definition) between the foreign exchange markets. Historical examples are the gold-standard system (1873-1914) and the Bretton-Woods system (1944-1976). The paper studies some characteristics of another historical example: international bimetallism (see that definition).

Markov Switching Model: An autoregressive model where the process linking a present value to its lags is an hidden Markov chain defined by its transition matrix

SOM Algorithm: An unsupervised technique of classification (Kohonen, 1984) combining adaptive learning and neighbourhood to construct a very stable classification, with a more simple interpretation ('Kohonen maps') than other techniques.

Learning in Feed-Forward Artificial Neural Networks I

Lluís A. Belanche Muñoz

Universitat Politècnica de Catalunya, Spain

INTRODUCTION

The view of artificial neural networks as adaptive systems has led to the development of ad-hoc generic procedures known as *learning rules*. The first of these is the Perceptron Rule (Rosenblatt, 1962), useful for single layer feed-forward networks and linearly separable problems. Its simplicity and beauty, and the existence of a *convergence theorem* made it a basic departure point in neural learning algorithms. This algorithm is a particular case of the Widrow-Hoff or *delta* rule (Widrow & Hoff, 1960), applicable to continuous networks with no hidden layers with an error function that is quadratic in the parameters.

BACKGROUND

The first truly useful algorithm for feed-forward multilayer networks is the *backpropagation* algorithm (Rumelhart, Hinton & Williams, 1986), reportedly proposed first by Werbos (1974) and Parker (1982). Many efforts have been devoted to enhance it in a number of ways, especially concerning speed and reliability of convergence (Haykin, 1994; Hecht-Nielsen, 1990). The backpropagation algorithm serves in general to compute the gradient vector in all the first-order methods, reviewed below.

Neural networks are trained by setting values for the network parameters \underline{w} to minimize an error function $E(\underline{w})$. If this function is quadratic in \underline{w} , then the solution can be found by solving a linear system of equations (e.g. with Singular Value Decomposition (Press, Teukolsky, Vetterling & Flannery, 1992)) or iteratively with the delta rule. The minimization is realized by a variant of a *gradient descent* procedure, whose ultimate outcome is a local minimum: a \underline{w}^* from which any infinitesimal change makes $E(\underline{w}^*)$ increase, that may not correspond to one of the global minima. Different solutions are found by starting at different initial states. The process is also perturbed by round-

off errors. Given $E(\underline{w})$ to be minimized and an initial state \underline{w}^0 , these methods perform for each iteration the updating step:

$$\underline{w}^{i+1} = \underline{w}^i + \alpha_i \underline{u}^i \quad (1)$$

where \underline{u}^i is the *minimization direction* (the direction in which to move) and $\alpha_i \in \mathbb{R}$ is the *step size* (how far to make a move in \underline{u}^i), also known as the *learning rate* in earlier contexts. For convenience, define $\Delta \underline{w}^i = \underline{w}^{i+1} - \underline{w}^i$. Common stopping criteria are:

1. A maximum number of presentations of D (*epochs*) is reached.
2. A maximum amount of computing time has been exceeded.
3. The evaluation has been minimized below a certain tolerance.
4. The gradient norm has fallen below a certain tolerance.

LEARNING ALGORITHMS

Training algorithms may require information from the objective function only, the gradient vector of the objective function or the Hessian matrix of the objective function:

- *Zero-order* training algorithms make use of the objective function only. The most significant algorithms are *evolutionary algorithms*, which are global optimization methods (Goldberg, 1989).
- *First-order* training algorithms use the objective function and its gradient vector. Examples are *Gradient Descent*, *Conjugate Gradient* or *Quasi-Newton* methods, which are all local optimization methods (Luenberger, 1984).
- *Second-order* training algorithms make use of the objective function, its gradient vector and its Hessian matrix. Examples are *Newton's method*

and the *Levenberg-Marquardt algorithm*, which are local optimization methods (Luenberger, 1984).

First-order methods. The *gradient* $\nabla E(\underline{\mathbf{w}})$ of an s -dimensional function is the vector field of first derivatives of $E(\underline{\mathbf{w}})$ w.r.t. $\underline{\mathbf{w}}$,

$$\nabla E(\underline{\mathbf{w}}) = \left(\frac{\partial E(\underline{\mathbf{w}})}{\partial w_1}, \dots, \frac{\partial E(\underline{\mathbf{w}})}{\partial w_s} \right) \quad (2)$$

Here $s = \dim(\underline{\mathbf{w}})$. A linear approximation to $E(\underline{\mathbf{w}})$ in an infinitesimal neighbourhood of an arbitrary point $\underline{\mathbf{w}}^i$ is given by:

$$E(\underline{\mathbf{w}}) \approx E(\underline{\mathbf{w}}^i) + \nabla E(\underline{\mathbf{w}}^i) \cdot (\underline{\mathbf{w}} - \underline{\mathbf{w}}^i) \quad (3)$$

We write $\nabla E(\underline{\mathbf{w}}^i)$ for the gradient $\nabla E(\underline{\mathbf{w}})$ evaluated at $\underline{\mathbf{w}}^i$. These are the first two terms of the Taylor expansion of $E(\underline{\mathbf{w}})$ around $\underline{\mathbf{w}}^i$. In *steepest* or *gradient* descent methods, this local gradient alone determines the minimization direction $\underline{\mathbf{u}}^i$. Since, at any point $\underline{\mathbf{w}}^i$, the gradient $\nabla E(\underline{\mathbf{w}}^i)$ points in the direction of fastest increase of $E(\underline{\mathbf{w}})$, an adjustment of $\underline{\mathbf{w}}^i$ in the negative direction of the local gradient leads to its maximum decrease. In consequence the direction $\underline{\mathbf{u}}^i = -\nabla E(\underline{\mathbf{w}}^i)$ is taken.

In conventional steepest descent, the step size α_i is obtained by a *line search* in the direction of $\underline{\mathbf{u}}^i$: how far to go along $\underline{\mathbf{u}}^i$ before a new direction is chosen. To this end, evaluations of $E(\underline{\mathbf{w}})$ and its derivatives are made to locate some nearby local minimum. Line search is a move in the chosen direction $\underline{\mathbf{u}}^i$ to find the minimum of $E(\underline{\mathbf{w}})$ along it. For this one-dimensional problem, the simplest approach is to proceed along $\underline{\mathbf{u}}^i$ in small steps, evaluating $E(\underline{\mathbf{w}})$ at each sampled point, until it starts to increase. One often used method is a divide-and-conquer strategy, also called Brent's method (Fletcher, 1980):

1. Bracket the search by setting three points $a < b < c$ along $\underline{\mathbf{u}}^i$ such that $E(a\mathbf{u}^i) > E(b\mathbf{u}^i) < E(c\mathbf{u}^i)$. Since E is continuous, there is a local minimum in the line joining a to c .
2. Fit a parabola (a quadratic polynomial) to a, b, c .
3. Compute the minimum μ of the parabola in the line joining a to c . This value is an approximation of the minimum of E in this interval.

4. Set three new points a, b, c out of μ and the two points among the old a, b, c having the lowest E . Repeat from 2.

Although it is possible to locate the nearby global minimum, the cost can become prohibitively high. The line search can be replaced by a fixed step size α , which has to be carefully chosen. A sufficiently small α is required such that $\alpha \nabla E(\underline{\mathbf{w}}^i)$ is effectively very small and the expansion (3) can be applied. A too large value might cause to overshoot or lead to divergent oscillations and a complete breakout of the algorithm. On the other hand, very small values translate in a painfully slow minimization. In practice, a trial-and-error process is carried out.

A popular heuristic is a historic average of previous changes to exploit tendencies and add inertia to the descent, accomplished by adding a so-called *momentum* term $\beta_i \Delta \underline{\mathbf{w}}^{i-1}$, where $\Delta \underline{\mathbf{w}}^{i-1}$ is the previous weight update (Rumelhart, Hinton & Williams, 1986). This term helps to avoid or smooth out oscillations in the motion towards a minimum. In practice, it is set to a constant value $\beta \in (0.5, 1)$. Altogether, for steepest descent, the update equation (1) reads:

$$\underline{\mathbf{w}}^{i+1} = \underline{\mathbf{w}}^i + \alpha_i \underline{\mathbf{u}}^i + \beta \Delta \underline{\mathbf{w}}^{i-1} \quad (4)$$

where $\underline{\mathbf{u}}^i = -\nabla E(\underline{\mathbf{w}}^i)$ and $\Delta \underline{\mathbf{w}}^{i-1} = \underline{\mathbf{w}}^i - \underline{\mathbf{w}}^{i-1}$. This method is very sensitive to the chosen values for α_i and β , to the point that different values are required for different problems and even for different stages in the learning process (Toolenaar, 1990). The inefficiency of the steepest descent method stems from the fact that both $\underline{\mathbf{u}}^i$ and α_i are somewhat poorly chosen. Unless the first step is chosen leading straight to a minimum, the iterative procedure is very likely to wander with many small steps in zig-zag. Therefore, these methods are quite out of use nowadays. A method in which both parameters are properly chosen is the *conjugate gradient*.

Conjugate Gradient. This minimization technique (explained at length in Shewchuck, 1994) is based on the idea that a new direction $\underline{\mathbf{u}}^{i+1}$ should not spoil previous minimizations in the directions $\underline{\mathbf{u}}^i, \underline{\mathbf{u}}^{i-1}, \dots, \underline{\mathbf{u}}^1$. This is the case if we simply choose $\underline{\mathbf{u}}^i = -\underline{\mathbf{g}}^i$, where $\underline{\mathbf{g}}^i = \nabla E(\underline{\mathbf{w}}^i)$, as was found above for steepest descent. At most points on $E(\underline{\mathbf{w}})$, the gradient does *not* point directly towards the minimum. After a line minimization, the new gradient $\underline{\mathbf{g}}^{i+1}$ is orthogonal to the line

search direction, that is, $\mathbf{g}^{i+1} \cdot \mathbf{u}^i = 0$. Thus, successive search directions will also be orthogonal, and the error function minimization will proceed in zig-zag in a extremely slow advance to a minimum.

The solution to this problem lies in determining consecutive search directions \mathbf{u}^{i+1} in such a way that the component of the gradient parallel to \mathbf{u}^i (which has just been made to be zero, because we minimized in that direction) remains zero, so consecutive search directions complement each other, avoiding the possibility of spoiling the progress done in previous iterations.

Let us assume a line minimization has just been made along \mathbf{u}^i , starting from the current weights \mathbf{w}^i ; we have thus found a new point \mathbf{w}^{i+1} for which

$$\nabla E(\mathbf{w}^{i+1}) \cdot \mathbf{u}^i = 0 \quad (5)$$

holds. The next search direction \mathbf{u}^{i+1} is chosen to retain the property that the component of the gradient parallel to \mathbf{u}^i , remains zero:

$$\nabla E(\mathbf{w}^{i+1} + \alpha_i \mathbf{u}^{i+1}) \cdot \mathbf{u}^i = 0 \quad (6)$$

Expanding (6) to first order in α_i , and applying (5), we obtain the condition (Bishop, 1995):

$$\mathbf{u}^{i+1} \cdot H_{\mathbf{w}}(\mathbf{w}^{i+1}) \cdot \mathbf{u}^i = 0 \quad (7)$$

If the error surface is quadratic, (7) holds regardless of the value of α_i , because the Hessian is constant, and higher-order terms in the previous expansion vanish. Search directions $\mathbf{u}^{i+1}, \mathbf{u}^i$ fulfilling (7) are said to be *conjugate*. It can be proven that, in these conditions, it is possible to construct a sequence $\mathbf{u}^1, \dots, \mathbf{u}^s$ such that \mathbf{u}^s is conjugate to all previous directions, so that the minimum can be located in at most $s = \dim(\mathbf{w})$ steps.

The *conjugate gradient* technique departs from (1) but sets $\mathbf{u}^{i+1} = -\mathbf{g}^{i+1} + \beta_i \mathbf{u}^i$, setting $\mathbf{u}^1 = -\mathbf{g}^1$. It turns out that the β_i can be found without explicit knowledge of the Hessian and the various versions of conjugate gradient are distinguished by the manner in which the parameter β_i is set. For the *Polak-Ribière* updating:

$$\beta_i = \frac{\mathbf{g}^{i+1} \cdot (\mathbf{g}^{i+1} - \mathbf{g}^i)}{\mathbf{g}^i \cdot \mathbf{g}^i} \quad (8)$$

This is the inner product of the previous change in the gradient with the current gradient, divided by

the squared norm of the previous gradient. For the *Fletcher-Reeves* updating:

$$\beta_i = \frac{\mathbf{g}^{i+1} \cdot \mathbf{g}^{i+1}}{\mathbf{g}^i \cdot \mathbf{g}^i} \quad (9)$$

This is the ratio of the squared norm of the current gradient to the squared norm of the previous gradient. The α_i can be found by performing a line search (at each iteration step) to determine the optimal distance to move along the current train direction; that is, a line minimization of $\nabla E(\mathbf{w}^i + \alpha_i \mathbf{u}^i)$ w.r.t. α_i . This results in a particular case of steepest descent with momentum, where the parameters α_i, β_i are determined at each iteration. For a quadratic error surface $E(\mathbf{w})$, the method finds the minimum after at most $s = \dim(\mathbf{w})$ steps, without calculating the Hessian. In practice $E(\mathbf{w})$ may be far from being quadratic so the technique needs to be run for many iterations and augmented with a criterion to reset the search vector to the negative gradient direction $\mathbf{u}^{i+1} = -\mathbf{g}^{i+1}$ after every s steps (Press, Teukolsky, Vetterling & Flannery, 1992). The *scaled* version (Møller, 1993) takes some account of the non-quadratic nature of the error function. With these enhancements the method is generally believed to be fast and reliable. Contrary to steepest descent, it is relatively insensitive to its parameters—the line search for α_i and the variants of computing β_i —if they are set within a reasonable tolerance. There is some evidence that the Polak-Ribière formula accomplishes the transition to further iterations more efficiently: when it runs out of steam, it tends to reset the train direction \mathbf{u}^i to be down the local gradient, which is equivalent to beginning the conjugate-gradient procedure again.

The Newton training algorithm. First-order approximations ignore the curvature of $E(\mathbf{w})$. This can be fixed by considering the second-order term of the Taylor expansion around some \mathbf{w}^i in weight space:

$$E(\mathbf{w}) \approx E(\mathbf{w}^i) + \nabla E(\mathbf{w}^i) \cdot (\mathbf{w} - \mathbf{w}^i) + 1/2 (\mathbf{w} - \mathbf{w}^i) \cdot H_{\mathbf{w}}(\mathbf{w}^i) \cdot (\mathbf{w} - \mathbf{w}^i) \quad (10)$$

where $H_{\mathbf{w}} = \nabla \nabla E(\mathbf{w})$ is the Hessian $s \times s$ matrix of second derivatives, with components

$$H_{\mathbf{w}} = (h_{ij}), \quad h_{ij} = \frac{\partial^2 E(\mathbf{w})}{\partial w_i \partial w_j}.$$

Again, $H_{\underline{w}}(\underline{w}^i)$ indicates the evaluation of $H_{\underline{w}}$ in \underline{w}^i . The Hessian traces the curvature of the error function in weight space, portraying information about how $\nabla E_{\underline{w}}$ changes in different directions. Given a direction \underline{u}^i from \underline{w}^i , the product $H_{\underline{w}}(\underline{w}^i) \cdot \underline{u}^i$ is the rate of change of the gradient along \underline{u}^i from \underline{w}^i . Differentiating (10) w.r.t. \underline{w} , a local approximation of the gradient around \underline{w}^i is:

$$\nabla E_{\underline{w}} \approx \nabla E_{\underline{w}}(\underline{w}^i) + H_{\underline{w}}(\underline{w}^i) \cdot (\underline{w} - \underline{w}^i) \quad (11)$$

For points close to \underline{w}^i , (10) and (11) give reasonable approximations to the error function $E(\underline{w})$ and to its gradient. Setting (11) to zero, and solving for \underline{w} , one gets:

$$\underline{w}^* = -H^{-1}_{\underline{w}}(\underline{w}^i) \cdot \nabla E_{\underline{w}}(\underline{w}^i) \quad (12)$$

Newton's method uses the second partial derivatives of the objective function and hence is a second order method, finding the minimum of a quadratic function in just one iteration. The vector $H^{-1}_{\underline{w}}(\underline{w}^i) \cdot \nabla E_{\underline{w}}(\underline{w}^i)$ is known as the Newton train direction. Since higher-order terms have been neglected, the update formula (12) is used iteratively to find the optimal solution. An exact evaluation of the Hessian is computationally demanding if done at each stage of an iterative algorithm; the Hessian matrix must also be inverted. Further, the Newton train direction may move towards a maximum or a saddle point rather than a minimum (if the Hessian is not positive definite) and the error would not be guaranteed to be reduced. This motivates the development of alternative approximation methods.

The quasi-Newton training algorithm. As shown above, the iterative formula used in Newton's method is

$$\underline{w}^{i+1} = \underline{w}^i - H^{-1}_{\underline{w}}(\underline{w}^i) \cdot \nabla E_{\underline{w}}(\underline{w}^i) \quad (13)$$

The basic idea behind the quasi-Newton method is to approximate $H^{-1}_{\underline{w}}$ by another matrix G , using only the first partial derivatives of the error function. If $H^{-1}_{\underline{w}}$ is approximated by G , Equation (13) can be expressed as

$$\underline{w}^{i+1} = \underline{w}^i - \alpha^{*(i)} (G(\underline{w}^i) \cdot \nabla E_{\underline{w}}(\underline{w}^i)) \quad (14)$$

where $\alpha^{*(i)}$ can be considered as the optimal train rate along the train direction $G(\underline{w}^i) \cdot \nabla E_{\underline{w}}(\underline{w}^i)$. The gradient

descent direction method can be obtained by setting $G=I$.

In order to implement Equation (14), an approximate inverse G of the Hessian matrix is needed. Two commonly used algorithms are the Davidon-Fletcher-Powell (DFP) algorithm and the Broyden-Fletcher-Goldfarb-Shanno (BGFS) algorithm. The DFP algorithm is given by

$$G^{(i+1)} = G^{(i)} + \frac{(\underline{w}^{i+1} - \underline{w}^i) \otimes (\underline{w}^{i+1} - \underline{w}^i)}{(\underline{w}^{i+1} - \underline{w}^i) \cdot (\underline{g}^{i+1} - \underline{g}^i)} + \frac{[G^{(i)} \cdot (\underline{g}^{i+1} - \underline{g}^i)] \otimes (G^{(i)} \cdot [\underline{g}^{i+1} - \underline{g}^i])}{(\underline{g}^{i+1} - \underline{g}^i) \cdot G^{(i)} \cdot (\underline{g}^{i+1} - \underline{g}^i)}, \quad (15)$$

where \otimes denotes outer product, which is a matrix: the i,j component of $\underline{u} \otimes \underline{v}$ is $u_i v_j$. The BGFS algorithm is exactly the same, but with one additional term:

$$G^{(i+1)} = G^{(i)} + \frac{(\underline{w}^{i+1} - \underline{w}^i) \otimes (\underline{w}^{i+1} - \underline{w}^i)}{(\underline{w}^{i+1} - \underline{w}^i) \cdot (\underline{g}^{i+1} - \underline{g}^i)} + \frac{[G^{(i)} \cdot (\underline{g}^{i+1} - \underline{g}^i)] \otimes (G^{(i)} \cdot [\underline{g}^{i+1} - \underline{g}^i])}{(\underline{g}^{i+1} - \underline{g}^i) \cdot G^{(i)} \cdot (\underline{g}^{i+1} - \underline{g}^i)} + ((\underline{g}^{i+1} - \underline{g}^i) \cdot G^{(i)} \cdot (\underline{g}^{i+1} - \underline{g}^i)) \underline{v} \otimes \underline{v}, \quad (16)$$

where the vector \underline{v} is given by

$$\underline{v} = \frac{(\underline{w}^{i+1} - \underline{w}^i)}{(\underline{w}^{i+1} - \underline{w}^i) \cdot (\underline{g}^{i+1} - \underline{g}^i)} - \frac{G^{(i)} \cdot (\underline{g}^{i+1} - \underline{g}^i)}{(\underline{g}^{i+1} - \underline{g}^i) \cdot G^{(i)} \cdot (\underline{g}^{i+1} - \underline{g}^i)}. \quad (17)$$

It is generally recognized that the BFGS scheme is empirically superior to the DFP scheme (Press, Teukolsky, Vetterling & Flannery, 1992).

The Levenberg-Marquardt method, like the quasi-Newton methods, was designed to approach second-order training speed without computing the Hessian. When the objective function is a sum of squares (a very common case in neural networks), the Hessian matrix can be approximated as $H = J^T J$ and the gradient computed as $\underline{g} = J^T \underline{e}$, where J is the Jacobian matrix,

containing first derivatives of the network errors with respect to the weights, and \mathbf{g} is the vector of network errors. The Jacobian can be computed via standard backpropagation, a much less complex process than computing the Hessian.

The Levenberg-Marquardt algorithm uses this approximation to the Hessian in the following Newton-like update:

$$\mathbf{w}^{i+1} = \mathbf{w}^i - (J^T J + \mu I)^{-1} J^T \mathbf{g} \quad (18)$$

When the scalar μ is zero, this is Newton's method using the approximate Hessian matrix. When μ is large, this becomes gradient descent with a small step size. Newton's method is faster and more accurate near an error minimum, so the aim is to shift towards Newton's method as quickly as possible. Thus, μ is decreased after each successful step (reduction in objective function) and is increased only when a tentative step would increase it. When computation of the Jacobian becomes prohibitively high for big networks on a large number of training examples, the quasi-Newton method is preferred.

THE BACK-PROPAGATION ALGORITHM

This algorithm represented a breakthrough in connectionist learning due to the possibility to compute the gradient of the error function $\nabla E(\mathbf{w})$ recursively and efficiently. It is so-called because the components of the gradient concerning weights belonging to output units are computed first, and propagated backwards (toward the inputs) to compute the rest, in the order marked by the layers. Intuitively, the algorithm finds the extent to which the adjustment of one connection will reduce the error in the training examples (the partial derivative of the error function $E(\mathbf{w})$ with respect to the connection) and therefore the algorithm computes the full gradient vector $\nabla E(\mathbf{w})$.

To derive the algorithm, we introduce some notation. Given $f: R^n \rightarrow R^m$ the function to be approximated, we depart from a finite training set D of p samples of f ,

$$D = \{ \langle \mathbf{x}_1, \mathbf{y}_1 \rangle, \dots, \langle \mathbf{x}_p, \mathbf{y}_p \rangle \}, f(\mathbf{x}_\mu)_k + \varepsilon = y_{\mu,k} \quad (19)$$

For simplicity, we assume that the loss is the square error and define:

$$E(\mathbf{w}) = 1/2 \sum_{\mu=1}^p \sum_{k=1}^m (y_{\mu,k} - \zeta^{\mu,c+1}_k)^2 \quad (20)$$

where $\zeta^{\mu,c+1}_k = F_{\mathbf{w}}(\mathbf{x}_\mu)_k$ is the k -th component of the network's response to input pattern \mathbf{x}_μ (the network has $c+1$ layers, of which c are hidden). For a given input pattern \mathbf{x}_μ , define:

$$E^\mu(\mathbf{w}) = 1/2 \sum_{k=1}^m (y_{\mu,k} - \zeta^{\mu,c+1}_k)^2 \quad (21)$$

so that

$$E(\mathbf{w}) = \sum_{\mu=1}^p E^\mu(\mathbf{w}).$$

The computation of a single unit i in layer l , $1 \leq l \leq c+1$ upon presentation of pattern \mathbf{x}_μ to the network may be expressed $\zeta_i^{\mu,l} = g(\hat{\zeta}_i^{\mu,l})$, with g a smooth function—as the sigmoidals—and

$$\hat{\zeta}_i^{\mu,l} = \sum_j w_{ij}^l \zeta_j^{\mu,l-1}.$$

The first outputs are then defined $\zeta^{\mu,0}_i = x_{\mu,i}$. A single weight w_{ij}^l denotes the connection strength from neuron j in layer $l-1$ to neuron i in layer l , $1 \leq l \leq c+1$.

If the gradient-descent rule (1) with constant α is followed, then $\mathbf{u}^l = -\nabla E(\mathbf{w}^l)$. Together with (2), the increment Δw_{ij}^l in a single weight w_{ij}^l of \mathbf{w} is:

$$\Delta w_{ij}^l = -\alpha \frac{\partial E(\mathbf{w})}{\partial w_{ij}^l} = -\alpha \sum_{\mu=1}^p \frac{\partial E^\mu(\mathbf{w})}{\partial w_{ij}^l} = -\alpha \sum_{\mu=1}^p \Delta^\mu w_{ij}^l \quad (22)$$

We have:

$$\Delta^\mu w_{ij}^l = \frac{\partial E^\mu(\mathbf{w})}{\partial w_{ij}^l} = \frac{\partial E^\mu(\mathbf{w})}{\partial \zeta_i^{\mu,l}} \frac{\partial \zeta_i^{\mu,l}}{\partial \hat{\zeta}_i^{\mu,l}} \frac{\partial \hat{\zeta}_i^{\mu,l}}{\partial w_{ij}^l} \quad (23)$$

Proceeding from right to left in (23):

$$\frac{\partial \hat{\zeta}_i^{\mu,l}}{\partial w_{ij}^l} = \zeta_j^{\mu,l-1} \quad (24)$$

$$\frac{\partial \zeta_i^{\mu,l}}{\partial \hat{\zeta}_i^{\mu,l}} = \frac{dg(\hat{\zeta}_i^{\mu,l})}{d\hat{\zeta}_i^{\mu,l}} = g'(\hat{\zeta}_i^{\mu,l}) \quad (25)$$

Assuming g to be the logistic function with slope β :

$$g'(\hat{\zeta}_i^{\mu,l}) = \beta g(\hat{\zeta}_i^{\mu,l}) (1 - g(\hat{\zeta}_i^{\mu,l})) = \beta \zeta_i^{\mu,l} (1 - \zeta_i^{\mu,l}) \quad (26)$$

The remaining expression

$$\frac{\partial E^\mu(\mathbf{w})}{\partial \zeta_i^{\mu,l}}$$

is more delicate and constitutes the core of the algorithm. We develop two separate cases: $l=c+1$ and $l < c+1$. The first case corresponds to output neurons, for which an expression of the derivative is immediate from (21):

$$\frac{\partial E^\mu(\mathbf{w})}{\partial \zeta_i^{\mu,c+1}} = -(y_{\mu,i} - \zeta_i^{\mu,c+1}) \quad (27)$$

Incidentally, collecting all the results so far and assuming $c=0$ (no hidden layers), the *delta rule* for non-linear single-layer networks is obtained:

$$\Delta^\mu w_{ij} = \alpha \sum_{\mu=1}^p (y_{\mu,i} - \zeta_i^\mu) g'(\hat{\zeta}_i^\mu) \zeta_j^{\mu,0} = \alpha \sum_{\mu=1}^p \delta_i^\mu x_{\mu,j} \quad (28)$$

where the superscript l is dropped (since $c=0$), and $\delta_i^\mu = (y_{\mu,i} - \zeta_i^\mu) g'(\hat{\zeta}_i^\mu)$. Another name for the back-propagation algorithm is *generalized delta rule*. Consequently, for $l \geq 1$, the *deltas* (errors local to a unit) are defined as:

$$\delta_i^{\mu,l} = \frac{\partial E^\mu(\mathbf{w})}{\partial \hat{\zeta}_i^{\mu,l}} \quad (29)$$

For the output layer $l=c+1$, $\delta_i^{\mu,l} = (y_{\mu,i} - \zeta_i^\mu) g'(\hat{\zeta}_i^\mu)$. In case g is the logistic, we finally have:

$$\delta_i^{\mu,l} = (y_{\mu,i} - \zeta_i^{\mu,c+1}) \beta \zeta_i^{\mu,l} (1 - \zeta_i^{\mu,l}) \quad (30)$$

For the general case $l < c+1$, we proceed as follows:

$$\frac{\partial E^\mu(\mathbf{w})}{\partial \zeta_i^{\mu,l}} = \sum_k \frac{\partial E^\mu(\mathbf{w})}{\partial \zeta_k^{\mu+1,l}} \frac{\partial \zeta_k^{\mu+1,l}}{\partial \zeta_i^{\mu,l}} \quad (31)$$

Now $l < c+1$ means there is at least one more layer $l+1$ to the *right* of layer l which is *posterior* in the *feed-forward* computation, but that *precedes* l in the opposite direction. Therefore $\delta E^\mu(\mathbf{w})$ functionally depends on layer $l+1$ *before* than layer l , and the derivative can be split in two. The summation over k is due to the fact that $\delta E^\mu(\mathbf{w})$ depends on every neuron in layer $l+1$. Rewriting (31):

$$\frac{\partial E^\mu(\mathbf{w})}{\partial \zeta_i^{\mu,l}} = \sum_k \frac{\partial E^\mu(\mathbf{w})}{\partial \hat{\zeta}_k^{\mu+1,l}} \frac{\partial \hat{\zeta}_k^{\mu+1,l}}{\partial \zeta_i^{\mu,l}} = \sum_k \delta_k^{\mu,l+1} w_{ki}^{l+1} \quad (32)$$

since

$$\zeta_k^{\mu,l+1} = \sum_j w_{kj}^{l+1} \zeta_j^{\mu,l}$$

and thus

$$\frac{\partial \hat{\zeta}_k^{\mu,l+1}}{\partial \zeta_i^{\mu,l}} = w_{ki}^{l+1}.$$

Putting together (24), (25), (27) and (32) in (23):

$$\Delta^\mu w_{ij}^l = \frac{\partial E^\mu(\mathbf{w})}{\partial \zeta_i^{\mu,l}} \frac{\partial \zeta_i^{\mu,l}}{\partial \hat{\zeta}_i^{\mu,l}} \frac{\partial \hat{\zeta}_i^{\mu,l}}{\partial w_{ij}^l} = \delta_i^{\mu,l} \zeta_j^{\mu,l-1} \quad (33)$$

where

$$\delta_i^{\mu,l} = g'(\hat{\zeta}_i^{\mu,l}) \sum_k \delta_k^{\mu,l+1} w_{ki}^{l+1},$$

the deltas for the hidden units. We show the method (Fig. 1) in algorithmic form, for an *epoch* or presentation of the training set.

Figure 1. Back-propagation algorithm pseudo-code

```

for all  $\mu$  in  $1 \leq \mu \leq p$ 
  1. Forward pass. Present  $x^\mu$  and compute
     the outputs  $\zeta_i^{\mu,l}$  of all the units.
  2. Backward pass. Compute the deltas  $\delta_i^{\mu,l}$ 
     of all the units (the local gradients), as follows:
       
$$\underline{l=c+1}: \delta_i^{\mu,l} = g'(\zeta_i^{\mu,l}) (y_{\mu,l} - \zeta_i^{\mu,l})$$

       
$$\underline{l \leq c+1}: \delta_i^{\mu,l} = g'(\zeta_i^{\mu,l}) \sum_k \delta_k^{\mu,l+1} w_{ki}^{l+1}$$

  3.  $\Delta w_{ij}^{\mu,l} = \delta_i^{\mu,l} \zeta_j^{\mu,l-1}$ 
End
Update weights as  $\Delta w_{ij}^l = \alpha \sum_{\mu=1}^p \Delta w_{ij}^{\mu,l}$ 

```

CONCLUSION

The strong points of ANNs are the capacity to learn from examples, distributed computation, tolerance to partial failures and the possibility to use them as black-box models. The procedure used to carry out the training process in a neural network is called the training or learning algorithm. Since the objective function is a non linear function of the free parameters, it is not possible to find closed training algorithms for the minima. Preferred algorithms for the multilayer perceptron are the quasi-Newton and Levenberg-Marquardt methods, together with back-propagation to compute the gradient vector efficiently.

KEY TERMS

Artificial Neural Network: Information processing structure without global or shared memory that takes the form of a directed graph where each of the computing elements (“neurons”) is a simple processor with internal and adjustable parameters, that operates only when all its incoming information is available.

Back-Propagation: Algorithm for feed-forward multilayer networks that can be used to efficiently compute the gradient vector in all the first-order methods.

Feed-Forward Artificial Neural Network: Artificial Neural Network whose graph has no cycles.

First-Order Method: A training algorithm using the objective function and its gradient vector.

Learning Algorithm: Method or algorithm by virtue of which an Artificial Neural Network develops a representation of the information present in the learning examples, by modification of the weights.

Second-Order Method: A training algorithm using the objective function, its gradient vector and Hessian matrix.

Weight: A free parameter of an Artificial Neural Network, modified through the action of a Learning Algorithm to obtain desired responses to certain input stimuli.

Learning in Feed-Forward Artificial Neural Networks II

INTRODUCTION

Supervised Artificial Neural Networks (ANN) are information processing systems that adapt their functionality as a result of exposure to input-output examples. To this end, there exist generic procedures and techniques, known as *learning rules*. The most widely used in the neural network context rely in derivative information, and are typically associated with the Multilayer Perceptron (MLP). Other kinds of supervised ANN have developed their own techniques. Such is the case of Radial Basis Function (RBF) networks (Poggio & Girosi, 1989). There has been also considerable work on the development of *ad hoc* learning methods based on evolutionary algorithms.

BACKGROUND

The problem of learning an input/output relation from a set of examples can be regarded as the task of approximating an unknown function from a set of data points, which are possibly sparse. Concerning approximation by classical feed-forward ANN, these networks implement a parametric approximating function and have been shown to be able of representing generic classes of functions (as the continuous or integrable functions) to an arbitrary degree of accuracy. In general, there are three questions that arise when defining one such parameterized family of functions:

1. What is the most adequate parametric form for a given problem?
2. How to find the best parameters for the chosen form?
3. What classes of functions can be represented and how well?

The most typical problems in a ANN supervised learning process, besides the determination of the learn-

ing parameters themselves, include (Hertz, Krogh & Palmer, 1991), (Hinton, 1989), (Bishop, 1995):

1. The possibility of getting stuck in *local optima* of the cost function, in which conventional non-linear optimization techniques will stay forever. The incorporation of a global scheme (like multiple restarts or an annealing schedule) is surely to increase the chance of finding a better solution, although the cost can become prohibitively high. A feed-forward network has multiple equivalent solutions, created by weight permutations and sign flips. Every local minima in a network with a single hidden layer of h_1 units has $s(h_1) = h_1! 2^{h_1}$ equivalent solutions, so the chances of getting in the basin of attraction of one of them are reasonable high. The complexity of the error surface—especially in very high dimensions—makes the possibility of getting trapped a real one.
2. Long *training times*, *oscillations* and network *paralysis*. These are features highly related to the specific learning algorithm, and relate to bad or too general choices for the parameters of the optimization technique (such as the learning rate). The presence of saddle points—regions where the error surface is very flat—also provoke an extremely slow advance for extensive periods of time. The use of more advanced methods that dynamically set these and other parameters can alleviate the problem.
3. *Non-cumulative* learning. It is hard to take an already trained network and re-train it with additional data without losing previously learned knowledge.
4. The *curse of dimensionality*, roughly stated as the fact that the number of examples needed to represent a given function grows exponentially with the number of dimensions.
5. Difficulty of finding a *structure* in the training data, possibly caused by a very high dimension or a distorting pre-processing scheme.

6. Bad *generalization*, which can be due to several causes: the use of poor training data or attempts to extrapolate beyond them, an excessive number of hidden units, too long training processes or a badly chosen regularization. All of them can lead to an *overfitting* of the training data, in which the ANN adjusts the training set merely as an *interpolation* task.
7. Not amenable to *inspection*. It is generally arduous to interpret the knowledge learned, especially in large networks or with a high number of model inputs.

LEARNING IN RBF NETWORKS

A Radial Basis Function network is a type of ANN that can be viewed as the solution of a high-dimensional curve-fitting problem. Learning is equivalent to finding a surface providing the best fit to the data. The RBF network is a two-layered feed forward network using a linear transfer function for the output units and a radially symmetric transfer function for the hidden units. The computation of a hidden unit is expressed as the composition of two functions, as:

$$F_i(\mathbf{x}) = \{g(h(\mathbf{x}, \mathbf{w}_i)), \mathbf{w}_i \in R^n\}, \quad \mathbf{x} \in R^n \quad (1)$$

with the choice $h(\mathbf{x}, \mathbf{w}_i) = \|\mathbf{x} - \mathbf{w}_i\|/\theta$ (or other distance measure), with $\theta > 0$ a smoothing term, plus an activation g which very often is a monotonically decreasing response from the origin. These units are localized, in the sense that they give a significant response only in a neighbourhood of their centre \mathbf{w}_i . For the activation function a Gaussian $g(z) = \exp(-z^2/2)$ is a preferred choice.

Learning in RBF networks is characterized by the separation of the process in two consecutive stages (Haykin, 1994), (Bishop, 1995):

1. Optimize the free parameters of the hidden layer (including the smoothing term) using only the $\{\mathbf{x}\}_i$ in D . This is an *unsupervised* method that depends on the *input sample distribution*.
2. With these parameters found and frozen, optimize the $\{c_i\}_i$, the hidden-to-output weights, using the full information in D . This is a *supervised* method that depends on the given *task*.

There are many ways of optimizing the hidden-layer parameters. When the number of hidden neurons equals the number of patterns, each pattern may be taken to be a center of a particular neuron. However, the aim is to form a representation of the probability density function of the data, by placing the centres in only those regions of the input space where significant data are present. One commonly used method is the *k-means algorithm* (McQueen, 1967), which in turn is an approximate version of the maximum-likelihood (ML) solution for determining the location of the means of a mixture density of component densities (that is, maximizing the likelihood of the parameters with respect to the data). The Expectation-Maximization (EM) algorithm (Duda & Hart, 1973) can be used to find the exact ML solution for the means and covariances of the density. It seems that EM is superior to k-means (Nowlan, 1990). The set of centres can also be selected randomly from the set of data points.

The value of the smoothing term can be obtained from the clustering method itself, or else estimated a posteriori. One popular heuristic is:

$$\theta = \frac{d}{\sqrt{2M}} \quad (2)$$

where d is the maximum distance between the chosen centers and M is the number of centers (hidden units). Alternatively, the method of *Distance Averaging* (Moody and Darken, 1989) can be used, which is the global average over all Euclidean distances between the center of each unit and that of its nearest neighbor.

Once these parameters are chosen and kept constant, assuming the output units are linear, the (square) error function is quadratic, and thus the hidden-to-output weights can be fast and reliably found iteratively by simple gradient descent over the quadratic surface of the error function or directly by solving the minimum norm solution to the over determined least-squares data fitting problem (Orr, 1995).

The whole set of parameters of a RBF network can also be optimized with a global gradient descent procedure on all the free parameters at once (Bishop, 1995), (Haykin, 1994). This brings back the problems of local minima, slow training, etc, already discussed. However, better solutions can in principle be found, because the unsupervised solution focuses on esti-

minating the input probability density function, but the resulting disposition may not be the one minimizing the square error.

EVOLUTIONARY LEARNING ALGORITHMS

The alternative to derivative-based learning algorithms (DBLA) are Evolutionary Algorithms (EA) (Back, 1996). Although the number of successful specific applications of EA is counted by hundreds (see (Back, Fogel & Michalewicz, 1997) for a review), only Genetic Algorithms or GA (Goldberg, 1989) and, to a lesser extent, Evolutionary Programming (Fogel, 1992), have been broadly used for ANN optimization, since the earlier works using genetic algorithms (Montana & Davis, 1989). Evolutionary algorithms operate on a population of individuals applying the principle of *survival of the fittest* to produce better approximations to a solution. At each generation, a new population is created by selecting individuals according to their level of fitness in the problem domain and recombining them using operators borrowed from natural genetics. The offspring also undergo mutation. This process leads to the evolution of populations of individuals that are better suited to their environment than the individuals that they were created from, just as in natural adaptation.

There are comprehensive review papers and guides to the extensive literature on this subject: see (Shaffer, Whitley & Eshelman, 1992), (Yao, 1993), (Kuşçu & Thornton, 1994) and (Balakrishnan & Honavar, 1995). One of their main advantages over methods based on derivatives is the global search mechanism. A global method does not imply that the solution is not a local optimum; rather, it eliminates the possibility of getting *caught* in local optima. Another appealing issue is the possibility of performing the traditionally separated steps of determining the best architecture and its weights *at the same time*, in a search over the joint space of structures and weights. Another advantage is the use of potentially any cost measure to assess the goodness of fit or include structural information. Still another possibility is to embody a DBLA into a GA, using the latter to search among the space of structures and the DBLA to optimize the weights; this hybridization leads to extremely high computational costs. Finally, there is the use of EA solely for the numerical optimization problem. In the neural context, this is arguably the task

for which continuous EA are most naturally suited. However, it is difficult to find applications in which GA (or other EA, for that matter) have clearly outperformed DBLA for supervised training of feed-forward neural networks (Whitley, 1995). It has been pointed out that this task is inherently hard for algorithms that rely heavily on the recombination of potential solutions (Radcliffe, 1991). In addition, the training times can become too costly, even worse than that for DBLA.

In general, Evolutionary Algorithms –particularly, the continuous ones– are in need of specific research devoted to ascertain their general validity as alternatives to DBLA in neural network optimization. Theoretical as well as practical work, oriented to tailor specific EA parameters for this task, together with a specialized operator design should pave the way to a fruitful assessment of validity.

FUTURE TRENDS

Research in ANN currently concerns the development of *learning algorithms* for weight adaptation or, more often, the enhancement of existing ones. New *architectures* (ways of arranging the units in the network) are also introduced from time to time. Classical *neuron models*, although useful and effective, are lessened to a few generic function classes, of which only a handful of instances are used in practice.

One of the most attractive enhancements is the extension of neuron models to modern data mining situations, such as data heterogeneity. Although a feed-forward neural network can in principle approximate an arbitrary function to any desired degree of accuracy, in practice a pre-processing scheme is often applied to the data samples to ease the task. In many important domains from the real world, objects are described by a mixture of continuous and discrete variables, usually containing missing information and characterized by an underlying vagueness, uncertainty or imprecision. For example, in the well-known UCI repository (Murphy & Aha, 1991) over half of the problems contain *explicitly declared* nominal attributes, let alone other discrete types or fuzzy information, usually unreported. This heterogeneous information should not be treated in general as real-valued quantities. Conventional ways of encoding non-standard information in ANN include (Prechelt, 1994), (Bishop, 1995), (Fiesler & Beale, 1997):

Ordinal variables. These variables correspond to discrete (finite) sets of values wherein an ordering has been defined (possibly only partial). They are more than often treated as real-valued, and mapped equidistantly on an arbitrary real interval. A second possibility is to encode them using a *thermometer*. To this end, let k be the number of ordered values; k new *binary* inputs are then created. To represent value i , for $1 \leq i \leq k$, the leftmost $1, \dots, i$ units will be on, and the remaining $i+1, \dots, k$ off.

The interest in these variables relies in that they appear frequently in real domains, either as symbolic information or from processes that are discrete in nature. Note that an ordinal variable need not be numerical.

Nominal variables Nominal variables are unanimously encoded using a 1-out-of- k representation, being k the number of values, which are then encoded as the rows of the $I_{k \times k}$ identity matrix.

Missing values Missing information is an old issue in statistical analysis (Little & Rubin, 1987). There are several causes for the absence of a value. They are very common in Medicine and Engineering, where many variables come from on-line sensors or device measurements. Missing information is difficult to handle, especially when the lost parts are of significant size. It can be either removed (the entire case) or “filled in” with the mean, median, nearest neighbour, or encoded by adding another input equal to one only if the value is absent and zero otherwise. Statistical approaches need to make assumptions about or model the input distribution itself. The main problem with missing data is that we never know if all the efforts devoted to their estimation will revert, in practice, in better-behaved data. This is also the reason why we develop on the treatment of missing values as part of the general discussion on data characteristics. The reviewed methods pre-process the data to make it acceptable by models that otherwise would not accept it. In the case of missing values, the data is *completed* because the available neural methods only admit complete data sets.

Uncertainty. Vagueness, imprecision and other sources of uncertainty are considerations usually put aside in the ANN paradigm. Nonetheless, many variables in learning processes are likely to bear some form of uncertainty. In Engineering, for example, on-line sensors are likely to get old with time and continuous use, and this may be reflected in the quality of their measurements. In many occasions, the data at hand are imprecise for a manifold of reasons: technical

limitations, a veritable qualitative origin, or even we can be interested in introducing imprecision with the purpose of augmenting the capacity for abstraction or generalization (Esteva, Godo & García), possibly because the underlying process is believed to be less precise than the available measures.

In Fuzzy Systems theory there are explicit formalisms for representing and manipulating uncertainty, that is precisely what the system best models and manages. It is perplexing that, when supplying this kind of input/output data, we require the network to approximate the desired output in a very precise way. Sometimes the known value takes an interval form: “between 5.1 and 5.5”, so that any transformation to a real value will result in a loss of information. A more common situation is the absence of numerical knowledge. For example, consider the value “fairly tall” for the variable *height*. Again, Fuzzy Systems are comfortable, but for an ANN this is real trouble. The integration of symbolic and continuous information is also important because numeric methods bring higher *concretion*, whereas symbolic methods bring higher *abstraction*. Their combined use is likely to increase the flexibility of hybrid systems. For numeric data, an added flexibility is obtained by considering imprecision in their values, leading to fuzzy numbers (Zimmermann, 1992).

CONCLUSION

As explained at length in other chapters, derivative-based learning algorithms make a number of assumptions about the local error surface and its differentiability. In addition, the existence of local minima is often neglected or overlooked entirely. In fact, the possibility of getting caught in these minima is more than often circumvented by multiple runs of the algorithm (that is, multiple restarts from different initial points in weight space). This “sampling” procedure is actually an implementation of a very naïve stochastic process. A global training algorithm for neural networks is the evolutionary algorithm, a stochastic search training algorithm based on the mechanics of natural genetics and biological evolution. It requires information from the objective function, but not from the gradient vector or the Hessian matrix and thus it is a zero-order method. On the other hand, there is an emerging need to devise neuron models that properly handle different data types,

as is done in support vector machines (Shawe-Taylor & Cristianini, 2004), where kernel design is a current research topic.

KEY TERMS

Architecture: The number of artificial neurons, its arrangement and connectivity.

Artificial Neural Network: Information processing structure without global or shared memory that takes the form of a directed graph where each of the computing elements (“neurons”) is a simple processor with internal and adjustable parameters, that operates only when all its incoming information is available.

Evolutionary Algorithm: A computer simulation in which a population of *individuals* (abstract representations of candidate solutions to an optimization problem) are stochastically selected, recombined, mutated, and then removed or kept, based on their relative fitness to the problem.

Feed-Forward Artificial Neural Network: Artificial Neural Network whose graph has no cycles.

Learning Algorithm: Method or algorithm by virtue of which an Artificial Neural Network develops a representation of the information present in the learning examples, by modification of the weights.

Neuron Model: The computation of an artificial neuron, expressed as a function of its input and its weight vector and other local information.

Weight: A free parameter of an Artificial Neural Network, that can be modified through the action of a Learning Algorithm to obtain desired responses to certain input stimuli.

Learning Nash Equilibria in Non-Cooperative Games

Alfredo Garro

University of Calabria, Italy

INTRODUCTION

Game Theory (Von Neumann & Morgenstern, 1944) is a branch of applied mathematics and economics that studies situations (games) where self-interested interacting players act for maximizing their returns; therefore, the return of each player depends on his behaviour and on the behaviours of the other players. Game Theory, which plays an important role in the social and political sciences, has recently drawn attention in new academic fields which go from algorithmic mechanism design to cybernetics. However, a fundamental problem to solve for effectively applying Game Theory in real word applications is the definition of well-founded solution concepts of a game and the design of efficient algorithms for their computation.

A widely accepted solution concept of a game in which any cooperation among the players must be self-enforcing (non-cooperative game) is represented by the Nash Equilibrium. In particular, a Nash Equilibrium is a set of strategies, one for each player of the game, such that no player can benefit by changing his strategy unilaterally, i.e. while the other players keep their strategies unchanged (Nash, 1951). The problem of computing Nash Equilibria in non-cooperative games is considered one of the most important open problem in Complexity Theory (Papadimitriou, 2001). Daskalakis, Goldberg, and Papadimitriou (2005), showed that the problem of computing a Nash equilibrium in a game with four or more players is complete for the complexity class PPAD-Polynomial Parity Argument Directed version (Papadimitriou, 1991), moreover, Chen and Deng extended this result for 2-player games (Chen & Deng, 2005). However, even in the two players case, the best algorithm known has an exponential worst-case running time (Savani & von Stengel, 2004); furthermore, if the computation of equilibria with simple additional properties is required, the problem immediately becomes NP-hard (Bonifaci, Di Iorio, & Laura, 2005) (Conitzer & Sandholm, 2003) (Gilboa & Zemel, 1989) (Gottlob, Greco, & Scarcello, 2003).

Motivated by these results, recent studies have dealt with the problem of efficiently computing Nash Equilibria by exploiting approaches based on the concepts of learning and evolution (Fudenberg & Levine, 1998) (Maynard Smith, 1982). In these approaches the Nash Equilibria of a game are not statically computed but are the result of the evolution of a system composed by agents playing the game. In particular, each agent after different rounds will learn to play a strategy that, under the hypothesis of agent's rationality, will be one of the Nash equilibria of the game (Benaïm & Hirsch, 1999) (Carmel & Markovitch, 1996).

This article presents SALENE, a Multi-Agent System (MAS) for learning Nash Equilibria in non-cooperative games, which is based on the above mentioned concepts.

BACKGROUND

An n -person strategic game G can be defined as a tuple $G = (N; (A^i)_{i \in N}; (r^i)_{i \in N})$, where $N = \{1, 2, \dots, n\}$ is the set of players, A^i is a finite set of actions for player $i \in N$, and $r^i : A^1 \times \dots \times A^n \rightarrow \mathbb{R}$ is the payoff function of player i . The set A^i is called also the set of pure strategies of player i . The Cartesian product $\times_{i \in N} A^i = A^1 \times \dots \times A^n$ can be denoted by A and $r : A \rightarrow \mathbb{R}^N$ can denote the vector valued function whose i th component is r^i , i.e., $r(a) = (r^1(a), \dots, r^n(a))$, so it is possible to write (N, A, r) for short for $(N; (A^i)_{i \in N}; (r^i)_{i \in N})$.

For any finite set A^i the set of all probability distributions on A^i can be denoted by $\Delta(A^i)$. An element $\sigma^i \in \Delta(A^i)$ is a mixed strategy for player i .

A (Nash) equilibrium of a strategic game $G = (N, A, r)$ is an N -tuple of (mixed) strategies $\sigma = (\sigma^i)_{i \in N}$, $\sigma^i \in \Delta(A^i)$, such that for every $i \in N$ and any other strategy of player i , $\tau^i \in \Delta(A^i)$, $r^i(\tau^i, \sigma^{-i}) \leq r^i(\sigma^i, \sigma^{-i})$, where r^i denotes also the expected payoff to player i in the mixed extension of the game and σ^{-i} represents the mixed strategies in σ of all the other players. Basically, supposing that all the other players do not change their

strategies it is not possible for any player i to play a different strategy τ^i able to gain a better payoff of that gained by playing σ^i . σ^i is called a Nash equilibrium strategy for player i .

In 1951 J. F. Nash proved that a strategic (non-cooperative) game $G = (N, A, r)$ has at least a (Nash) equilibrium σ (Nash, 1951); in his honour, the computational problem of finding such equilibria is known as NASH (Papadimitriou, 1994).

SOFTWARE AGENTS FOR LEARNING NASH EQUILIBRIA

SALENE was conceived as a system for learning at least one Nash Equilibrium of a non-cooperative game given in the form $G = (N; (A^i)_{i \in N}; (r^i)_{i \in N})$. In particular, the system asks the user for:

- the number n of the players which defines the set of players $N = \{1, 2, \dots, n\}$;
- for each player $i \in N$, the related finite set of pure strategies A^i and his payoff function $r^i : A^1 \times \dots \times A^n \rightarrow \mathbb{R}$;
- the number k of times the players will play the game.

Figure 1. The class diagram of SALENE

Then, the system creates n agents, one associated to each player, and a referee. The agents will play the game G k times, after each match, each agent will decide the strategy to play in the next match to maximise his expected utility on the basis of his beliefs about the strategies that the other agents are adopting. By analyzing the behaviour of each agent in all the k matches of the game, SALENE presents to the user an estimate of a Nash Equilibrium of the game. The Agent paradigm has represented a “natural” way of modeling and implementing the proposed solution as it is characterized by several interacting autonomous entities (players) which try to achieve their goals (consisting in maximising their returns).

The class diagram of SALENE is shown in Figure 1.

The Manager Agent interacts with the user and it is responsible for the global behaviour of the system. In particular, after having obtained from the user the input parameters G and k , the Manager Agent creates both n Player Agents and a Referee Agent that coordinates and monitors the behaviours of the players. The Manager Agent sends to all the agents the definition G of the game then he asks the Referee Agent to orchestrate k matches of the game G . In each match, the Referee Agent asks each Player Agent which pure strategy he has decided to play, then, after having acquired the strategies from all players, the Referee Agent communicates to each Player Agent both the strategies played and the payoffs gained by all players. After playing k matches of the game G the Referee Agent communicates all the data about the played matches to the Manager Agent which analyses it and properly presents the obtained results to the user.

A Player Agent is a rational player that, given the game definition G , acts to maximise his expected utility in each single match of G without considering the overall utility that he could obtain in a set of matches. In particular the behaviour of the Player Agent i can be described by the following main steps:

1. In the first match the Player Agent i chooses to play a pure strategy randomly generated considering all the pure strategies playable with the same probability: if $|A^i|=m$ the probability of choosing a pure strategy $s \in A^i$ is $1/m$;
2. The Player Agent i waits for the Referee Agent to ask him which strategy he wants to play, then he communicates to the Referee Agent the chosen

pure strategy as computed in step 1 if he is playing his first match or in step 4 otherwise;

3. The Player Agent waits for the Referee Agent to communicate him both the pure strategies played and the payoffs gained by all players;
4. The Player Agent decides the mixed strategy to play in the next match. In particular, the Player Agent updates the beliefs about the mixed strategies currently adopted by the other players and consequently recalculate the strategy able to maximise his expected utility. Basically, the Player Agent i tries to find the strategy $\sigma^i \in \Delta(A^i)$, such that for any other strategy $\tau^i \in \Delta(A^i)$, $r^i(\tau^i, \sigma^{-i}) \leq r^i(\sigma^i, \sigma^{-i})$ where r^i denotes his expected payoff and σ^{-i} represents his beliefs about the mixed strategies currently adopted by all the other players, i.e. $\sigma^{-i} = (\sigma^j)_{j \in N, j \neq i}$, $\sigma^j \in \Delta(A^j)$. In order to evaluate σ^i for each other player $j \neq i$ the Player Agent i considers the pure strategies played by the player j in all the previous matches and computes the frequency of each pure strategy, this frequency distribution will be the estimate for σ^j . If there is at least an element in the actually computed set $\sigma^{-i} = (\sigma^j)_{j \in N, j \neq i}$ that differs from the set σ^{-i} as computed in the previous match, the Player Agent i solves the inequality $r^i(\tau^i, \sigma^{-i}) \leq r^i(\sigma^i, \sigma^{-i})$ that is equivalent to solve the optimization problem $P = \{\max(r^i(\sigma^i, \sigma^{-i})), \sigma^i \in \Delta(A^i)\}$. It is worth noting that P is a linear optimization problem, actually, given the set σ^{-i} , $r^i(\sigma^i, \sigma^{-i})$ is a linear objective function in σ^i (see the game definition reported in the Background Section), and with $|A^i| = m$ $\sigma^i \in \Delta(A^i)$ is a vector $\chi \in \mathbb{R}^m$ such that $\sum_{s \in M} \chi_s = 1$ and for every $s \in M$ $\chi_s \geq 0$, so the constraint $\sigma^i \in \Delta(A^i)$ is a set of $m+1$ linear inequalities. P is solved by the Player Agent by using an efficient method for solving problems in linear programming, in particular the predictor-corrector method of Mehrotra (1992), whose complexity is polynomial for both average and worst case. The obtained solution for σ^i is a pure strategy because it is one of the vertices of the polytope which defines the feasible region for P . The obtained strategy σ^i will be played by the Player Agent i in the next match; $r^i(\sigma^i, \sigma^{-i})$ represents the expected payoff to player i in the next match;
5. back to step 2.

It is worth noting that a Player Agent for choosing the mixed strategy to play in each match of G does not need to know the payoff functions of the others players, in fact, for solving the optimization problem P it only needs to consider the strategies which have been played by the other players in all the previous matches.

The Manager Agent, receives from the Referee Agent all the data about the k matches of the game G and computes an estimate of a Nash Equilibrium of G , i.e. an N -tuple $\sigma = (\sigma^i)_{i \in N}$, $\sigma^i \in \Delta(A^i)$. In particular, in order to estimate σ^i (the Nash equilibrium strategy of the player i), the Manager Agent computes, on the basis of the pure strategies played by the player i in each of the k match, the frequency of each pure strategy: this frequency distribution will be the estimate for σ^i . The so computed set $\sigma = (\sigma^i)_{i \in N}$, $\sigma^i \in \Delta(A^i)$ will be then properly proposed to the user together with the data exploited for its estimation.

SALENE has been implemented using JADE (Bellifemine, Poggi, & Rimassa, 2001), a software framework allowing for the development of multi-agent systems and applications conforming to FIPA standards (FIPA, 2006), and tested on different games that differ from each other both in the number and in the kind of Nash Equilibria. The experiments have demonstrated that:

- if the game has $p > 1$ Pure Nash Equilibria and $s > 0$ Mixed Nash Equilibria the agents converge in playing one of the p Pure Nash Equilibria; in these cases, as the behaviour of each Player Agent converges with probability one to a Nash Equilibrium of the game, the learning process *converges in behaviours to equilibrium* (Foster & Young, 2003);
- if the game has only Mixed Nash Equilibria, while the behaviour of the Player Agents does not converge to an equilibrium, the time-average behaviour, i.e. the empirical frequency with which each player chooses his strategy, may converge to one of the mixed Nash Equilibria of the game; that is the learning process may *converge in time average to equilibrium* (Foster and Young, 2003).

In the next Section the main aspects related to the convergence properties of the approach/algorithm

exploited by the SALENE agents for learning Nash Equilibria are discussed in a more general discussion about current and future research efforts.

FUTURE TRENDS

Innovative approaches, as SALENE, based on the concepts of learning and evolution have shown great potential for modelling and efficiently solving non-cooperative games. However, as the solutions of the games (e.g. Nash Equilibria) are not statically computed but are the result of the evolution of a system composed by interacting agents, there are several open problems mainly related to the accuracy of the provided solution that need to be tackled to allow these approaches to be widely exploited in concrete business application.

The approach exploited in SALENE, which derives from the *Fictitious Play* (Robinson, 1951) approach, efficiently solves the problem of learning a Nash Equilibrium in non-cooperative games which have at least one Pure Nash Equilibrium: in such a case the behaviour of the players exactly converges to one of the Pure Nash Equilibria of the game (*convergence in behaviours to equilibrium*). On the contrary, if the game has only Mixed Nash Equilibria, the convergence of the learning algorithm is not ensured. Computing *ex ante* when this case happens is quite costly as it requires to solve the following problem: “Determining whether a strategic game has only Mixed Nash Equilibria”, which is equivalent to: “Determining whether a strategic game does not have any Pure Nash Equilibria”. This problem is Co-NP complete as its complement “Determining whether a strategic game has a Pure Nash Equilibrium” is NP complete (Gottlob, Greco, & Scarcello, 2003). As witnessed by the conducted experiments, when a game has only Mixed Nash Equilibria there are still some cases in which, while the behaviour of the players does not converge to an equilibrium, the time-average behaviour, i.e. the empirical frequency with which each player chooses his strategy, converges to one of the Mixed Nash Equilibria of the game (*convergence in time average to equilibrium*).

Nevertheless, there are some cases in which there is neither *convergence in behaviour* neither *convergence in time average to equilibrium*; an example of such a case is the *fashion game* of Shapley (1964). An important open problem is then represented by the characterization of the classes of games for which the learning algorithm

adopted in SALENE converges; more specifically, the classes of games for which the algorithm: (a) *converges in behaviours to equilibrium* (which implies the *convergence in time average to equilibrium*), (b) only *converges in time average to equilibrium*; (c) does not converge neither *in behaviours* neither *in time average*. Currently, it has been demonstrated that the algorithm converges *in behaviours* or *in time average to equilibrium* for the following classes of games:

- zero-sum games (Robinson, 1951);
- games which are solvable by iterated elimination of strictly dominated strategies (Nachbar, 1990);
- potential games (Monderer & Shapley, 1996);
- 2xN games, i.e. games with 2 players, 2 strategies for one player and N strategies for the other player (Berger, 2005).

Future efforts will be geared towards: (i) completing the characterization of the classes of games for which the learning algorithm adopted in SALENE converges and evaluating the complexity of solving the *membership problem* for such a classes; (ii) evaluating different learning algorithms and their convergence properties; (iii) letting the user ask for the computation of Nash Equilibria with simple additional properties.

More in general, a wide adoption of the emerging agent-based approaches for solving games which model concrete business applications will depend on the accuracy and the convergence properties of the provided solutions; both aspects still need to be fully investigated.

CONCLUSION

The complexity of NASH, the problem consisting in computing Nash Equilibria in non-cooperative games, is still debated, but even in the two players case, the best known algorithm has an exponential worst-case running time. SALENE, the proposed MAS for learning Nash Equilibria in non-cooperative games, can be conceived as a heuristic and efficient method for computing at least one Nash Equilibria in a non-cooperative game represented in its normal form; actually, the learning algorithm adopted by the Player Agents has a polynomial running time for both average and worst case. SALENE can be then fruitfully exploited for

efficiently solving non-cooperative games which model interesting concrete problems ranging from classical economic and finance problems to the emerging ones related to the economic aspects of the Internet such as TCP/IP congestion, selfish routing, and algorithmic mechanism design.

KEY TERMS

Computational Complexity Theory: A branch of the theory of computation in computer science which studies how the running time and the memory requirements of an algorithm increase as the size of the input to the algorithm increases.

Game Theory: A branch of applied mathematics and economics that studies situations (games) where

self-interested interacting players act for maximizing their returns.

Heuristic: In computer science, a technique designed to solve a problem which allows for gaining computational performance or conceptual simplicity potentially at the cost of accuracy and/or precision of the provided solutions to the problem itself.

Nash Equilibrium: A solution concept of a game where no player can benefit by changing his strategy unilaterally, i.e. while the other players keep theirs unchanged; this set of strategies and the corresponding payoffs constitute a Nash Equilibrium of the game.

NP-Hard Problems: Problems that are intrinsically harder than those that can be solved by a nondeterministic Turing machine in polynomial time.

Non-Cooperative Games: A game in which any cooperation among the players must be self-enforcing.

Payoffs: Numeric representations of the utility obtainable by a player in the different outcomes of a game.

Learning-Based Planning

INTRODUCTION

Automated Planning (AP) studies the generation of action sequences for problem solving. A problem in AP is defined by a state-transition function describing the dynamics of the world, the initial state of the world and the goals to be achieved. According to this definition, AP problems seem to be easily tackled by searching for a path in a graph, which is a well-studied problem. However, the graphs resulting from AP problems are so large that explicitly specifying them is not feasible. Thus, different approaches have been tried to address AP problems. Since the mid 90's, new planning algorithms have enabled the solution of practical-size AP problems. Nevertheless, domain-independent planners still fail in solving complex AP problems, as solving planning tasks is a PSPACE-Complete problem (Bylander, 94).

How do humans cope with this planning-inherent complexity? One answer is that our experience allows us to solve problems more quickly; we are endowed with learning skills that help us plan when problems are selected from a stable population. Inspired by this idea, the field of learning-based planning studies the development of AP systems able to modify their performance according to previous experiences.

Since the first days, Artificial Intelligence (AI) has been concerned with the problem of Machine Learning (ML). As early as 1959, Arthur L. Samuel developed a prominent program that learned to improve its play in the game of checkers (Samuel, 1959). It is hardly surprising that ML has often been used to make changes in systems that perform tasks associated with AI, such as perception, robot control or AP. This article analyzes the diverse ways ML can be used to improve AP processes. First, we review the major AP concepts and summarize the main research done in learning-based planning. Second, we describe current trends in applying

ML to AP. Finally, we comment on the next avenues for combining AP and ML and conclude.

BACKGROUND

The languages for representing AP tasks are typically based on extensions of first-order logic. They encode tasks using a set of actions that represents the state-transition function of the world (the planning domain) and a set of first-order predicates that represent the initial state together with the goals of the AP task (the planning problem). In the early days of AP, STRIPS was the most popular representation language. In 1998 the Planning Domain Definition Language (PDDL) was developed for the first International Planning Competition (IPC) and since that date it has become the standard language for the AP community. In PDDL (Fox & Long, 2003), an action in the planning domain is represented by: (1) the action preconditions, a list of predicates indicating the facts that must be true so the action becomes applicable and (2) the action postconditions, typically separated in *add* and *delete* lists, which are lists of predicates indicating the changes in the state after the action is applied.

Before the mid '90s, automated planners could only synthesize plans of no more than 10 actions in an acceptable amount of time. During those years, planners strongly depended on speedup techniques for solving AP problems. Therefore, the application of search control became a very popular solution to accelerate planning algorithms. In the late 90's, a significant scale-up in planning took place due to the appearance of the reachability planning graphs (Blum & Furst, 1995) and the development of powerful domain independent heuristics (Hoffman & Nebel, 2001) (Bonet & Geffner, 2001). Planners using these approaches could often synthesize 100-action plans just in seconds.

At the present time, there is not such dependence on ML for solving AP problems, but there is a renewed interest in applying ML to AP motivated by three factors: (1) IPC-2000 showed that knowledge-based planners significantly outperform domain-independent planners. The development of ML techniques that automatically define the kind of knowledge that humans put in these planners would bring great advances to the field. (2) Domain-independent planners are still not able to cope with real-world complex problems. On the contrary, these problems are often solved by defining ad hoc planning strategies by hand. ML promises to be a solution to automatically defining these strategies. And, (3) there is a need for tools that assist in the definition, validation and maintenance of planning-domain models. At the moment, these processes are still done by hand.

LEARNING-BASED PLANNING

This section describes the current ML techniques for improving the performance of planning systems. These techniques are grouped according to the target of learning: search control, domains-specific planners, or domain models.

Learning Search Control

Domain-independent planners require high search effort, so search-control knowledge is frequently used to reduce this effort. Hand-coded control knowledge has proved to be useful in many domains, however is difficult for humans to formalize it, as it requires specific knowledge of the planning domains and the planner structure. Since AP's early days, diverse ML techniques have been developed with the aim of automatically learning search-control knowledge. A few examples of these techniques are macro-actions (Fikes, Hart & Nilsson, 1972), control-rules (Borrajó & Veloso, 1997), and case-based and analogical planning (Veloso, 1994).

At the present, most of the state-of-the-art planners are based on heuristic search over the state space (12 of the 20 participants in IPC-2006 used this approach). These planners achieve impressive performance in many domains and problems, but their performance strongly depends on the definition of a good domain-independent heuristic function. These heuristics are computed solving a simplified version of the planning

task, which ignores the delete list of actions. The solution to the simplified task is taken as the estimated cost for reaching the task goals. These kinds of heuristics provide good guidance across the wide range of different domains. However, they have some faults: (1) in many domains, these heuristic functions vastly underestimate the distance to the goal leading to poor guidance, (2) the computation of the heuristic values of the search nodes is too expensive, and (3) these heuristics are non-admissible so heuristics planners do not find good solutions in terms of plan quality.

Since evaluating a search node in heuristic planning is so time consuming, (De la Rosa, García-Olaya & Borrajó, 2007) proposed using Case-based Reasoning (CBR) to reduce the number of explored nodes. Their approach stores sequences of abstracted state transitions related to each particular object in a problem instance. Then, with a new problem, these sequences are retrieved and re-instantiated to support a forward heuristic search, deciding the node ordering for computing its heuristic value.

In the last years, other approaches have been developed to minimize the negative effects of the heuristic through ML: (Botea, Enzenberger, Müller & Schaeffer, 2005) learned off-line macro-actions to reduce the number of evaluated nodes by decreasing the depth of the search tree. (Coles & Smith, 2007) learned on-line macro-actions to escape from plateaus in the search tree without any exploration. (Yoon, Fern & Givan, 2006) proposed using an inductive approach to correct the domain-independent heuristic in those domains based on learning a supplement to the heuristic from observations of solved problems in these domains.

All these methods for learning search-control knowledge suffer from the utility problem. Learning too much control knowledge can actually be counterproductive because the difficulty of storing and managing the information and the difficulty of determining which information to use when solving a particular problem can interfere with efficiency.

Learning Domain-Specific Planners

An alternative approach to learning search control consists of learning domain-specific planning programs. These programs receive as input a planning problem of a fixed domain and return a plan that solves the problem.

The first approaches to learn domain-specific planners were based on supervised inductive learning; they used genetic programming (Spector, 1994) and decision-list learning (Kharon, 1999), but they were not able to reliably produce good results. Recently, (Winner & Veloso, 2003) presented a different approach based on generalizing an example plan into a domain-specific planning program and merging the resulting source code with the previous ones.

Domain-specific planners are also represented as policies, i.e., pairs of state and the preferred action to be executed in the state. Relational Reinforcement Learning (RRL) (Dzeroski, Raedt & Blockeel, 1998) has aroused interest as an efficient approach for learning policies for relational domains. RRL includes a set of learning techniques for computing the optimal policy for reaching the given goals by exploring the state space through trial and error. The major benefit of these techniques is that they can be used to solve problems whether the action model is known or not. In the other hand, since RRL does not explicitly include the task goals in the policies, new policies have to be learned every time a new goal has to be achieved, even if the dynamics of the environment has not changed.

In general, domain-specific planners have to deal with the problem of generalization. These techniques build planning programs from a given set of solved problems so cannot theoretically guarantee solving subsequent problems.

Learning Domain Models

No matter how efficient a planner is, if it is fed with a defective domain model, it will return defective plans. Designing, encoding and maintaining a domain model is very laborious. At the time being, planners are the only tool available to assist in the development of an AP domain model, but planners are not designed specifically for this purpose. Domain model learning studies ML mechanisms to automatically acquire the planning action schemas (the action preconditions and post-conditions) from observations of action executions.

Learning domain models in deterministic environments is a well-studied problem; diverse inductive learning techniques have been successfully applied to automatically define the actions schema from observations (Shen & Simon, 1989), (Benson, 1997), (Yang, Wu & Jiang, 2005), (Shahaf & Amir, 2006). In stochastic environments, this problem becomes more

complex. Actions may result in innumerable different outcomes, so more elaborated approaches are required. (Pasula, Zettlemoyer & Kaelbling, 2004) presented the first specific algorithm to learn simple stochastic actions without conditional effects. This algorithm is based on three levels of learning: the first one consists of deterministic rule-learning techniques to induce the action preconditions. The second one relies on a search for the set of action outcomes that best fits the execution examples, and; the third one consists of estimating the probability distributions over the set of action outcomes. But, stochastic planning algorithms do not need to consider all the possible actions outcomes. (Jimenez & Cussens 2006) proposed to learn complex action-effect models (including conditions) for only the relevant action outcomes. Thus, planners generate robust plans by covering only the most likely execution outcome while leaving others to be completed when more information is available.

In deterministic environments, (Shahaf & Amir, 2006) introduced an algorithm that exactly learns STRIPS action schemas even if the domain is only partially observable. But, in stochastic environments, there is still no general efficient approach to learn action model.

FUTURE TRENDS

Since the appearance of the first PDDL version in IPC-1998, the standard planning representation language has evolved to bring together AP algorithms and real-world planning problems. Nowadays, the PDDL 3.0 version for the IPC-2006 includes numeric state variables to support quality metrics, durative actions that allow explicit time representation, derived predicates to enrich the descriptions of the system states, and soft goals and trajectory constraints to express user preferences about the different possible plans without discarding valid plans. But, most of these new features are not handled by the state-of-the-art planning algorithms: The existing planners usually fail solving problems that define quality metrics. The issue of goal and trajectory preferences has only been initially addressed. Time and resources add such extra complexity to the search process that a real-world problem becomes extremely difficult to solve. New challenges for the AP community are those related to developing new planning algorithms and heuristics to deal with these kinds of problems. As

it is very difficult to find an efficient general solution, ML must play an important role in addressing these new challenges because it can be used to alleviate the complexity of the search process by exploiting regularity in the space of common problems.

Besides, the state-of-the-art planning algorithms need a detailed domain description to efficiently solve the AP task, but new applications like controlling underwater autonomous vehicles, Mars rovers, etc. imply planning in environments where the dynamics model may be not easily accessible. There is a current need for planning systems to be able to acquire information of their execution environment. Future planning systems have to include frameworks that allow the integration of the planning and execution processes together with domain modeling techniques.

Traditionally, learning-based planners are evaluated only against the same planner but without learning, in order to prove their performance improvement. Additionally, these systems are not exhaustively evaluated; typically the evaluation only focuses on a very small number of domains, so these planners are usually quite fragile when encountering new domains. Therefore, the community needs a formal methodology to validate the performance of the new learning-based planning systems, including mechanisms to compare different learning-based planners.

Although ML techniques improve planning systems, existing research cannot theoretically demonstrate that they will be useful in new benchmark domains. Moreover, for time being, it is not possible to formally explain the underlying meaning of the learned knowledge (i.e., does the acquired knowledge subsume task decomposition? a goal ordering? a solution path?). This point reveals that future research in AP and ML will also focus on theoretical aspects that address these issues.

CONCLUSION

Generic domain-independent planners are still not able to address the complexity of real planning problems. Thus, most planning systems implemented in applications require additional knowledge to solve the real planning tasks. However, the extraction and compilation of this specific knowledge by hand is complicated.

This article has described the main last advances in developing planners successfully assisted by ML

techniques. Automatic learned knowledge is useful for AP in diverse ways: it helps planners in guiding search processes, in completing domain theories or in specifying particular solutions to a particular problem. However, the learning-based planning community can not only focus on developing new learning techniques but also on defining formal mechanisms to validate its performance against other generic planners and against other learning-based planners.

KEY TERMS

Control Rule: *IF-THEN* rule to guide the planning search-tree exploration.

Derived Predicate: Predicate used to enrich the description of the states that is not affected by any of the domain actions. Instead, the predicate truth values are derived by a set of rules of the form **if** formula(x) **then** predicate(x).

Domain Independent Planner: Planning system that addresses problems without specific knowledge of the domain, as opposed to *domain-dependent planners*, which use domain-specific knowledge.

Macro-Action: Planning action resulting from combining the actions that are frequently used together in a given domain. Used as control knowledge to speed up plan generation.

Online Learning: Knowledge acquisition during a problem-solving process with the aim of improving the rest of the process.

Plateau: Portion of a planning search tree where the heuristic value of nodes is constant or does not improve.

Policy: Mapping between the world states and the preferred action to be executed in order to achieve a given set of goals.

Search Control Knowledge: Additional knowledge introduced to the planner with the aim of simplifying the search process, mainly by pruning unexplored portions of the search space or by ordering the nodes for exploration.

A Longitudinal Analysis of Labour Market Data with SOM

Patrick Rousset
CEREP, France

Jean-Francois Giret
CEREP, France

INTRODUCTION

The aim of this paper is to present a typology of career paths in France drawn up with the Kohonen algorithm and its extension to a clustering method of life history analysis based on the use of Self Organizing Maps (SOMs). Several methods have previously been presented for transforming qualitative into quantitative information so as to be able to apply clustering algorithms such as SOMs based on the Euclidean distance. Our approach consists in performing quantitative encoding on labor market situation proximities across time. Using SOMs, the preservation of the topology also makes it possible to check whether this new method of encoding preserves the particularities of the life history according to our economic approach to careers. Lastly, this quantitative encoding preprocessing, which can be easily applied to analysis methods of life history, completes the set of methods extending the use of SOM to qualitative data.

BACKGROUND

Several methods are generally used to study the dynamic aspects of careers. The first method, which estimates some reduced-form transition models, has been extensively used in labor microeconometrics, using event-history models for continuous-time data or discrete-time panel data with Markov processes. Those of the second kind, which include the method presented here, are sequence analysis methods dealing with complex information about individual labor market histories, such as the various states undergone, the duration of the spells, multiple transitions between the states, etc.. The idea was to empirically generate a statistical typology of sequences by performing cluster analysis (Lebart, 2006). This method thus makes it pos-

sible to define “cluster paths” constituting endogenous variables and explained in terms of individual characteristics such as gender, educational level or parental socio-economic status. The optimal matching method, which has been widely used in social science since the pioneering paper by Abott (Abbott & Hrycak, 1990), is an attractive solution for analysing longitudinal data of this kind. The basic idea underlying this method is to take a pair of sequences and calculate the cost of transforming them into each other by performing a series of elementary operations (insertion, deletion and substitution). However, this method has been heavily criticized because it may be difficult to determine the values of these elementary operations. Here we adopt another strategy. First, in order to classify sequences into groups, we have defined a measure of the distance between each trajectory, which is coherent with our data and with some well-known theoretical hypotheses in the field of labor economics. We then use Self Organizing Maps (the Kohonen algorithm) for classification and purposes.

Self Organizing Maps (see Kohonen, 2001, Fort, 2006) are known to be a powerful clustering and projection method. Since this method accounts efficiently for changes occurring with time, SOMs yield accurate predictions (see for example Cottrell, Girard & Rousset, 1998, Dablemont, Simon, Lendasse, Ruttiens, Blayo & Verleysen, 2003, Souza, Barreto & Mota, 2005). Life histories can be considered as a qualitative record of information, while SOMs are based on Euclidean distance. Many attempts have been made to transform qualitative variables into quantitative ones: using for example the Burt description (see the KACM presentation in Cottrell & Letremy, 1995) or using the multidimensional scaling (Miret, Garcia-Lagos, Joya, Arazoza & Sandoval, 2005). In our approach, the quantitative recoding focuses on the proximity between items considering particularities of the data (a life his-

tory) according to our economic approach. When the preprocessing of recoding is performed, Self Organizing Maps is a useful clustering tool, first considering its pre-mentioned clustering and projection qualities and also because of its ability to make the efficiency of our new encode emerge.

CLUSTERING LIFE HISTORY WITH SOM

An Example of a Life History

Career Paths

Labor economists have generally assumed that the beginning of a career results from a matching process (Jovanovich, 1979). Employers and job seekers lack information about each other: employers need to know how productive their potential employee is and job applicants want to know whether the characteristics of the job correspond to their expectations. Job turnover and temporary employment contracts can therefore be viewed as the consequences of this trial-by-error process. However, individuals' first employment situations may also act as a signal of employability to the labor market. For example, a long spell of unemployment during the first years in a person's career may be interpreted by potential employers as sign of low work efficiency; whereas working at a temp agency may be regarded as a sign of motivation and adaptability. This is consistent with the following path dependency hypothesis: the influence of past job experience on the subsequent career depends on the "cost" associated with the change of occupational situation. However, empirical studies have shown that employers mainly recruit on the basis of recent work experience (Allaire, Cahuzac & Tahar, 2000). The effects of less recent employment situations on a person's career therefore decrease over time.

Data

The data used in this study were based on the "Generation 98" survey carried out by Céreq: 22 000 young people who had left initial training in 1998 at all levels and in all training specializations were interviewed in spring 2001 and 2003 and autumn 2005. This sample

was representative of the 750 000 young people leaving the education system for the first time that year in France. This survey provided useful information about the young people's characteristics (their family's socio-economic status, age, highest grade completed, highest grade attended, discipline, any jobs taken during their studies, work placement) and the month-by-month work history from 1998 to 2005. We therefore have a complete and detailed record of the labor market status of the respondents during the 88-month period from July 1998 to November 2005. Employment spells were coded as follows, depending on the nature of the labor contract: 1 = permanent labor contract, 2 = fixed term contract, 3 = apprenticeship contract, 4 = public temporary labor contract, 5 = interim/templing). Other unemployed situations were coded as follows: 6 = unemployment, 7 = inactivity, 8 = military service, 9 = at school.

Preprocessing Phase: Life History Encoding

The encoding of the trajectories involved a two-step preprocessing phase : defining a distance between states including time dynamics and the resulting quantitative encoding of trajectories. These two steps refer to the specificity of the data set structures of life history samples: the variables items (the states) are some qualitative information while the variables order records some quantitative information (the timing and the duration of events).

The Distance Between Situations

Working with pairs (state, time), called situations, allows to include the time dynamics in the proximities between occupational states. The proximity between two situations is measured on the basis of their common future, in line with our Economic approach. A situation is assumed as a potential for its own future, depending on its influence on this future. The similarity between two situations is deduced from comparisons between their referring potential. The *potential future* P^S of a situation S among n monthly periods and p states is defined as the $p \times n$ dimensional vector given in (1). Its components P_s^S are the product of terms ϕ and β . ϕ measures the flow between situation S and any situation S' as the empirical probability of reaching S' starting

from S . It is also the empirical probability of an individual i being in any future situation S' conditionally of being at the present in S . The coefficient of temporal inertia β weights the influence of S' on P^S according to the Economic approach. It is a decreasing function of the time delay $(t' - t)$. In the career paths application, the function chosen is the inverse of the delay and 0 for the past. Lastly, α ensures that potential futures P_s will be profiles. The natural distance between situations is therefore the χ^2 distance between their potential future profiles.

$$P_{S=(s,t)} = \frac{1}{\alpha(t)} (\mathbf{0}, \dots, \mathbf{0}, \underbrace{\beta(t')\Phi_{S=(s,t)}^{S'=(1,t')}, \beta(t')\Phi_S^{S'=(2,t')}, \dots, \beta(t')\Phi_S^{S'=(9,t')}}_{t' \geq t}, \dots, \underbrace{\beta(T)\Phi_S^{S'=(1,T)}, \dots, \beta(T)\Phi_S^{S'}, \dots, \beta(T)\Phi_S^{S'=(9,T)}}_T) \quad (1)$$

where

$$\Phi_{S=(s,t)}^{S'=(s',t')} = \frac{\sum_i \chi_s \chi_{s'}}{\sum_i \chi_s} \quad 1$$

$$\beta(t,t') = \frac{1}{t'-t+1}$$

and

$$\alpha^{-1}(t) = \sum_{S'} \beta(S') \Phi_S^{S'}$$

The Trajectory Encoding

In the present case of equi-weighting, the inertia of the space of situations results from the distances previously computed. The principal components of inertia, called here principal events, can therefore be deduced. The term “event” refers to a combination of the point in time, the duration and the occupational status. The quantitative encoding of trajectories proposed here results from their description in the “events” space.

The process used here is in line with J.P. Benzécri's one (Benzécri, 1973), which explains how: when considering a set of situations $\{S^i\}$, its center of gravity G and the matrix recording squares of distance (d^{ij}) between elements S^i and S^j , one can deduce the matrix of scalar products Δ between any vectors GS^i

with the formula (2). Applying to the situations, the principal components of inertia (the principal events) are computed as the principal component vectors of the matrix Δ .

Trajectories can then be described in the principal events space: performing the traditional binary encoding (3) of the trajectory T_i is equivalent to performing a linear encoding through the situations (4) and then also through the principal events E (5).

$$\Delta_j^{j'} = GS^j \cdot GS^{j'} = -\frac{1}{2} [d^{\ddot{j}j'} - d^{j\cdot} - d^{\cdot j'} + d^{\cdot\cdot}] \quad (2)$$

$$T_i = (\underbrace{0, \dots, 0, 1, 0, \dots, 0, 0, \dots, 0, 1, 0, \dots, 0}_{\text{time}=1}, \underbrace{\dots, 0, \dots, 0, 1, 0, \dots, 0}_{9 \text{ positions}}, \underbrace{\dots, 0, \dots, 0, 1, 0, \dots, 0}_{\text{time}=9}) \quad (3)$$

$$T_i = \sum_{S=(s,t)} \alpha_{(S)}(0, \dots, \underbrace{0, 1, 0, \dots, 0}_{\text{position: } s^*t}) \quad (4)$$

$$T_i = \sum_S \alpha_S (\sum_e \beta_e^S E_e) = \sum_e \gamma_e E_e \quad (5)$$

CLASSIFICATION OF LIFE HISTORIES WITH SOM: A TYPOLOGY OF CAREER PATHS IN FRANCE AND ECONOMIC INTERPRETATIONS

The result of the typology of career paths in France using Self Organizing Maps with a 10x10 grid is presented in Figure 1. In each unit of the map, a chronogram describes the characteristics of the class (the career path). Chronograms show the evolution in time of the proportional contribution (in percentage) of each state to the classes. On the one hand, the SOM topology reflects the continuity of the evolution in time. On the other hand, similarities between situations give rise to the mixing of classes (see for example cluster 95) or proximities on the map between two clusters (for example, between clusters 71 and 72 – eighth line, first and second column) although few individuals are in the same state at the same time. The map thus makes it possible to assess the efficiency of the encoding process.

The Kohonen map displays a concise vision of the types of career paths occurring during the first seven years of working life. In general, most of the clusters describe a direct school-to-work transition process.

Figure 1. Typology of career paths with SOM: each unit on the map gives a chronogram of the evolution in time of the proportional contribution (as a percentage) of any occupational position. Two populations of closed units have similar chronogram.

which can be characterized by an immediate access to a permanent contract or an indirect access during the first few years. In the upper-left-hand corner of the map, mainly the five clusters of the two first lines, career paths are characterized by a high level of access to employment with permanent contracts. Young people rapidly gained access to a permanent contract and kept it until the end of the observation period. In upper-right-hand corner of the map, access to a permanent contract was less direct: during the first year, young people first obtained a temporary contract or spent ten months in compulsory military service before obtaining a permanent contract. the upper part of the map, the bottom part describes career paths with longer period of temporary contracts and/or unemployment. In the lower-right-hand corner, access to a permanent contract is becoming rare during the first few years. However, more than ninety per cent of young people have obtained a final permanent position (in the last column of the map). In the bottom lines, a five-year public policy contract called “Emploi Jeunes” features

strongly instead of the classical fixed term contract. The lower-left-hand corner of the map shows more unstable trajectories which end in a temporary position: seven years after leaving school, people have a temporary contract (in the last two clusters in the first column) or are unemployed (second and third cells on the last line). The chronograms situated in the middle-left-hand part of the map highlight how the longitudinal approach is interesting to understand the complexity of transition processes: the young people here were directly recruited for a permanent job, but five or six years after graduating, they lost this permanent job. This turn of events can be explained by the strong change in the economic environment which occurred during this period; the years 2003 and 2004 correspond to a dramatic growth of youth unemployment on the French labor market.

What role does each individual characteristic play in the development of these career paths? Several factors may explain the labor market opportunities of school-leavers: human capital factors, parents' social class,

Figure 2. Career path typology by educational levels

and other factors responsible for inequalities on the labor market, such as parents' nationality and gender. The distribution of these characteristics was included graphically in each cell on the map. Figure 2, which gives the distribution in terms of educational level, clearly shows that educational level strongly affected the career path. Higher educational graduates feature much more frequently in the upperleft-hand corner of the map, whereas school leavers without any qualifications occur more frequently in the bottom part. Figure 3 shows a similar pattern as far as gender is concerned: there are much higher percentages of females than males in the most problematic career paths, which suggests the occurrence of gender segregation or discriminatory practices on the French labor market. The differences are less conspicuous as far as the father's nationality is concerned (Figure 4). However, the results obtained here also suggests that children with French parents have better chances than the others of finding "safe" career paths.

Figure 3. Career path typology by gender

Figure 4. Career path typology by father's nationality

FUTURE TRENDS

The relevance of the method presented here concerns both aspects: the preprocessing and SOMs' result. The advantages of SOM depend on the distance chosen, which must enable the associated algorithm to preserve the proximities between situations. The relevance of the preprocessing stage in the method will therefore be confirmed if it enhances the reliability of the SOMs (Debodt, Cottrell & Verleysen, 2002, and Rousset, Guinot & Maillet, 2006, have presented a method of measuring and a method of increase reliability, respectively). On the other hand, the reliability also depends on the choice of the future weighting function, function β in formula (1). By consequence, function β could be determined here with a view to the reliability of the SOM results. But unfortunately, in general, this approach may be counter-productive in some cases. In the case of career paths, for example, it would lead to weighting the long term future, which would increase the robustness but would not be suitable from the point of view of the Economic investigation. This problem arises in many general contexts where the main effects of the present on the future are short term effects, whereas the reliability increases in the long term. The main criterion used to choose function β must therefore be the topic of interest.

Further studies are now required to improve the reliability of this method: first function β needs to be defined more closely and secondly, the validity of the method needs to be tested after enhancing the reliability that of the SOM topology obtained after performing the preprocessing step described above). It might also be worth investigating the use of Markovian models to define function β in particular, as well as to study career paths in general. This method will also have to be applied in the future to other samples.

CONCLUSION

The aim of this study was to analyze the early career of French schools leavers using Self Organizing Maps. This empirical analysis showed that career paths are strongly segmented. Although most of the "career paths" studied were characterized by stabilization on the labor market at some point or another, some of them show the great difficulties encountered by labor market entrants. Obtaining a permanent contract does not

actually guarantee life-long employment. In addition, the econometric analysis carried out in the second part of this study shows that the diversity of career paths can be partly explained by the educational levels and individual characteristics of school leavers.

In the present method of analyzing information on individuals' trajectories in time through a finite number of states, two important aspects are combined: the encoding of the data and the analysis of the data presented in the form of SOMs. The first aspect avoids the well known problem of skew present with qualitative encoding, including when it is linked to the evolution in time. Self organizing maps are a natural approach to the data analysis, since this tool combines the advantages of clustering and representation methods. The method described here turns out to be an efficient means of investigating changes with time and the proximities between situations. In addition, the preservation of the topology was found to be a useful property, which makes it possible to assess the efficiency of the recoding. In conclusion, the method presented here could easily be used to analyze any life history.

KEY TERMS

Careers Paths: Sequential monthly position among several pre-defined working categories.

Distibutional Equivalency: Property of a distance that allows to group two modalities of the same variable having identical profiles into a new modality weighted with the sum of the two weights.

Markov Process: Stochastic process in wich the new state of a system depends on the previous state or a finite set of previous states.

Optimal Matching: Statistical method issued from biology able to compare two sequences from a predefined cost of substitution.

Preservation of Topology: After learning, observations associated to the same class or to « close » classes according to the definition of the neighborhood and given by the network structure are « close » according to the distance in the input space.

Self-Organizing Maps by Kohonen: A neural network unsupervised method of vector quantization widely used in classification. Self-Organizing Maps are a much appreciated for their topology preservation property and their associated data representation system. These two additive properties come from a pre-defined organization of the network that is at the same time a support for the topology learning and its representation.

χ^2 Distance: Distance having certain specific properties such as the distibutional equivalency.

Managing Uncertainties in Interactive Systems

Qiyang Chen

John Wang

Montclair State University, USA

INTRODUCTION

To adapt users' input and tasks an interactive system must be able to establish a set of assumptions about users' profiles and task characteristics, which is often referred as user models. However, to develop a user model an interactive system needs to analyze users' input and recognize the tasks and the ultimate goals users trying to achieve, which may involve a great deal of uncertainties. In this chapter the approaches for handling uncertainty are reviewed and analyzed. The purpose is to provide an analytical overview and perspective concerning the major methods that have been proposed to cope with uncertainties.

Approaches for Handling Uncertainties

For a long time, the Bayesian model has been the primary numerical approach for representation and inference with uncertainty. Several mathematical models that are different from the probability prospective have also been proposed. The main ones are Shafer-Dempster's Evidence Theory (Belief Function) (Shafer, 1976; Dempster, 1976) and Zadeh's Possibility Theory (Zadeh, 1984). There have also been some attempts to handle the problem of incomplete information using classical logic. Many approaches to default reasoning logic have been proposed, and study of non-monotonic logic has gained much attention. These approaches can be classified into two categories: numerical approaches and non-numerical approaches.

1. *Probability and Bayesian Theory*. There is support for the theoretical necessity and justification of using a probability framework for knowledge representation, evidence combination and propagation, learning ability, and clarity of explanation (Buchana and Smith, 1988). Bayesian processing remains the fundamental idea underlying many

new proposals that claim to handle uncertainty efficiently.

In all the practical developments to date, the Bayesian formula and probability values have been used as some kind of coefficients to augment deterministic knowledge represented by production rules (Barr and Feigenbaum, 1982). Some intuitive methods for combination and propagation of these values have been suggested and used. One such case is the use of Certainty Factors (CF) in MYCIN (Shortliffe and Buchanan, 1976). Rich also use a simplified CF approach in user modeling system GROUNDY (Rich, 1979).

However, some objections against such probabilistic methods of accounting for uncertainty have been raised (Karnal and Lemmer, 1986). One of the main objections is that these values lack any definite semantics because of the way they have been used. Using a single number to summarize uncertainty information has always been a contested issue (Heckerman, 1986).

The Bayesian approach requires that each piece of evidence be conditionally independent. It has been concluded that the assumptions of conditional independence of the evidence under the hypotheses are inconsistent with the other assumptions of exhaustive and mutually exclusive space of hypotheses. Specifically, Pednault *et al.* (1981) show that, under these assumptions, a probabilistic update could take place if there were more than two competing hypotheses. Pearl (1985) suggests that the assumption of conditional independence of the evidence under the negation of the hypotheses is over-restrictive. For example, if the inference process contains multiple paths linking the evidence to the same hypothesis, the independence is violated. Similarly, the required mutual exclusiveness and exhaustiveness of the hypotheses are not very realistic. This assumption would not hold if more than one hypothesis occurred simultaneously and is as restrictive as the single-default assumption of the simplest

diagnosing systems. This assumption also requires that every possible hypothesis is known *a priori*. It would be violated if the problem domain were not suitable to a closed-world assumption.

Perhaps the most restrictive limitation of the Bayesian approach is its inability to represent ignorance. The Bayesian view of probability does not allow one to distinguish uncertainty from ignorance. One cannot tell whether a degree of belief was directly calculated from evidence or indirectly inferred from an absence of evidence. In addition, this method requires a large amount of data to determine the estimates for prior and conditional probabilities. Such a requirement becomes manageable only when the problem can be represented as a sparse Bayesian network that is formed by a hierarchy of small clusters of nodes. In this case, the dependencies among variables (nodes in the network) are known, and only the explicitly required conditional probabilities must be obtained (Pearl, 1988).

2. *The Dempster-Shafer Theory of Evidence.* The Dempster-Shafer theory, proposed by Shafer (Shafer, 1976), was developed within the framework of Dempster's work on upper and lower probabilities induced by a multi-valued mapping (Dempster, 1967). Like Bayesian theory, this theory relies on degrees of belief to represent uncertainty. However, it allows one to assign a degree of belief to subsets of hypotheses. According to the Dempster-Shafer theory, the feature of multi-valued mapping is the fundamental reason for the inability of applying the well-known theorem of probability that determines the probability density of the image of one-to-one mapping (Cohen, 1983). In this context, the lower probability is associated with the degree of belief and the upper probability with a degree of plausibility. This formalism defines certainty as a function that maps subsets of a proposition space on the $[0,1]$ scale. The sets of partial beliefs are represented by mass distributions of a unit of belief across the space of propositions. These distributions are called the basic probability assignment. The total certainty over the space is 1. A non-zero BPA can be given to the entire proposition space to represent the degree of ignorance. The certainty of any proposition is then represented by the interval characterized by upper and lower probabilities.

Dempster's rule of combination normalizes the intersection of the bodies of evidence from the two sources by the amount of non-conflictive evidence between the sources.

This theory is attractive for several reasons. First, it builds on classical probability theory, thus inheriting much of its theoretical foundations. Second, it seems not to over-commit by not forcing precise statements of probabilities: its probabilities do not seem to provide more information than is really available. Third, it reflects the degree of ignorance of the probability estimate. Fourth, the Dempster-Shafer theory provides rules for combining probabilities and thus for propagating measures through the system. This also is one of the most controversial points since the propagation method is an extension of the multiplication rule for independent events. Because many applications involve dependent events, the rule might be inapplicable by classical statistical criteria. The tendency to assume that events are independent unless proven otherwise has stimulated a large proportion of the criticism of probability approaches. Dempster-Shafer theory suffers the same problem (Bhatnager and Kanal, 1986).

In addition, there are two problems with Dempster-Shafer approach. The first problem is computational complexity. In the general case, the evaluation of the degree of belief and upper probability requires exponential time in the cardinality of the hypothesis set. This complexity is caused by the need for enumerating all the subsets of a given set. The second problem in this approach results from the normalization process presented in both Dempster's and Shafer's work. Zadeh has argued that this normalization process can lead to incorrect and counter-intuitive results (Zadeh, 1984). By removing the conflicting parts of the evidence and normalizing the remaining parts, important information may be discarded rather than utilized adequately. Dubois and Prade (1985) have also shown that the normalization process in the rule of evidence combination creates a sensitivity problem, where assigning a zero value or a very small value to a basic probability assignment causes very different results.

Based on Dempster-Shafer theory, Garvey *et al.* (1982) proposed an approach called Evidential Reasoning that adopts the evidential interpretation of the degree of belief and upper probabilities. This approach defines the likelihood of a proposition as a subinterval of the

unit interval $[0,1]$. The lower bound of this interval is the degree of support of the proposition and the upper bound is its degree of plausibility. When distinct bodies of evidence must be pooled, this approach uses the same Dempster-Shafer techniques, requiring the same normalization process that was criticized by Zadeh (Zadeh, 1984).

3. *Fuzzy Sets and Possibility Theory.* The theory of possibility was proposed independently by Zadeh, as a development of fuzzy set theory, in order to handle vagueness inherent in some linguistic terms (Zadeh, 1978). For a given set of hypotheses, a possibility distribution may be defined in a way that is very similar to that of a probability distribution. However, there is a qualitative difference between the probability and possibility of an event. The difference is that a high degree of possibility does not imply a high degree of probability, nor does a low degree of probability imply a low degree of possibility. However, an impossible event must also be improbable. More formally, Zadeh defined the concept of a possibility distribution.

The concept of possibility theory has been built upon fuzzy set theory and is well suited for representing the imprecision of vague linguistic predicates. The vague predicate induces a fuzzy set and the corresponding possibility distribution. From a semantic point of view, the values restricted by a possibility distribution are more or less all the eligible values for a linguistic variable. This theory is completely feasible for every element of the universe of discourse.

4. *Theory of Endorsement.* A different approach to uncertainty representation was proposed by Cohen (Cohen, 1983), which is based on a qualitative theory of "endorsement." According to Cohen, the records of the factors relating to one's certainty are called endorsements. Cohen's model of endorsement is based on the explicit recording of the justifications for a statement, normally requiring a complex data structure of information about the source. Therefore, this approach maintains the uncertainty. The justification is classified according to the type of evidence for a proposition, the possible actions required to solve the uncertainty of that evidence, and other related features.

Endorsements can provide a good mechanism for the explanations of reasoning, since they create and maintain the entire history of justifications (*i.e.*, reasons for believing or disbelieving a proposition) and the relevance of any proposition with respect to a given goal. Endorsements are divided into five classes: rules, data, task, conclusion, and resolution. Cohen points out that the main difference between the numerical approaches and the endorsement-based approach, specifically with respect to chains of inferences, is that reasoning in the former approach is entirely automatic and non-reflective, while the latter approach provides more information for reasoning about uncertainty. Consequently, reasoning in the latter approach can be controlled and determined by the quality and availability of evidence.

Endorsements provide the information necessary to many aspects of reasoning about uncertainty. Endorsements are used to schedule sure tasks before unsure ones, to screen tasks before activating them, to determine whether a proposition is certain enough for some purpose, and to suggest new tasks when old ones fail to cope with uncertainty. Endorsements distinguish different kinds of uncertainty, and tailor reasoning to what is known about uncertainty. However, Bonissone and Tong (1995) argue that combinations of endorsements in a premise (*i.e.*, proposition), propagation of endorsements to a conclusion, and ranking of endorsements must be explicitly specified for each particular context. This creates potential combinatorial problems.

5. *Assumption based reasoning and non-monotonic logic:* In the reasoned-assumptions approach proposed by Doyle (1979), the uncertainty embedded in an implication rule is removed by listing all the exceptions to that rule. When this is not possible, assumptions are used to show the *typicality* of a value (*i.e.*, default values) and defeasibility of a rule (*i.e.*, liability to defeat of reason). In classical logic, if a proposition C can be derived from a set of propositions S, and if S is a subset of T, then C can also be derived from T. As a system's premises increase, its possible conclusions at least remain constant and more likely increase. Deductive systems with this property are called monotonic. This kind of logic lacks tools for describing how to revise a formal theory to deal with inconsistencies caused by new information. McDermott and Dole proposed a non-monotonic

logic to cope with this problem (McDemott and Doyle, 1980).

When an assumption used in the deductive process is found to be false, non-monotonic mechanisms must be used to keep the integrity of the statements (Doyle, 1979). However, this approach lacks facilities for computing degrees of belief. Bonissone and Tong (1995) suggest that assumption-based systems can cope with cases of incomplete information, but they are inadequate in handling the imprecise information. In particular, they cannot integrate probabilistic measures with reasoned assumptions. Furthermore, such systems rely on the precision of the defaulted values. On the other hand, when specific information is missing, the system should be able to use analogous or relevant information inherited from some higher-level concept. This surrogate for the missing information is generally fuzzy or imprecise and provides limited constraints on the value of the missing information.

In the inference system employing non-monotonic logic, assumptions are made that may have to be revised in the light of new information. They have the property that at any given inference stage, more than one mutually consistent set of conclusions can be derived from the available data and possible assumptions. Such conclusions may be invalidated as new data is considered to be incompatible with some default assumptions. The inference system requires that justifications for any conclusion are recorded during the inference process and used for dependency-directed backtracking during the revision of beliefs. This is implemented by the Truth Maintenance System (TMS) (Dole, 1979).

The weakness of non-monotonic logic is that in standard non-monotonic logic the only message conveyed by a contradiction is that a piece of information previously believed true is actually false (for the time being). However, the real contents of the inconsistency being discovered may not be as reliable as was assumed, or it may be that a subject is not in a well-ordered state, or a mixture of both (Bhatnagar and Kanal, 1986). In addition, since the TMS examines the new information one piece at a time, it lacks the ability to detect *noise input* that should be ignored. This weakness is crucial to the task of pattern recognition (Chen and Norcio, 1997).

CONCLUSION

This chapter analyzes approaches of handling them in an adaptive human computer interface. Each approach can only deal with a particular type of uncertainty problems effectively. The interface system needs more comprehensive approach for uncertainty management due to various sources of uncertainties in human machine dialog. Especially, since human-machine dialog tend to be context-dependent, the management of uncertainty must provide a pattern-formatted view for user modeling. In other word, a user modeling system must examine the user input based the context of the dialog to obtain a complete and consistent user profiles. . Some non-traditional approaches have been proposed to handle uncertainties in interactive systems, such as neural networks and generic algorithms (Chen and Norcio 1997), because they have strong ability of pattern recognition and classification. However, the conversion between non-numerical user input and numerical input for neural network processing still involves a great deal of uncertainties.

KEY TERMS

Bayesian Theory: Also known as Bayes' rule or Bayes' law. It is a result in probability theory, which relates the conditional and marginal probability distributions of random variables. In some interpretations of probability, Bayes' theory tells how to update or revise beliefs in light of new evidences.

Default Reasoning: A non-monotonic logic proposed by Raymond Reiter to formalize reasoning with default assumptions. Default reasoning can express facts like "by default, something is true"; by contrast, standard logic can only express that something is true or that something is false. This is a problem because reasoning often involves facts that are true in the majority of cases but not always. A classical example is: "birds typically fly". This rule can be expressed in

standard logic either by “all birds fly”, which is inconsistent with the fact that penguins do not fly, or by “all birds that are not penguins and not ostriches and ... fly”, which requires all exceptions to the rule to be specified. Default logic aims at formalizing inference rules like this one without explicitly mentioning all their exceptions

Non-Monotonic Logic: A formal logic whose consequence relation is not monotonic. Most studied formal logics have a monotonic consequence relation, meaning that adding a formula to a theory never produces a reduction of its set of consequences. Intuitively, monotonicity indicates that learning a new piece of knowledge cannot reduce the set of what is known. A monotonic logic cannot handle various reasoning tasks such as reasoning by default.

Possibility Theory: A mathematical theory for dealing with certain types of uncertainty and is an alternative to probability theory. Professor Lotfi Zadeh first introduced possibility theory in 1978 as an extension of his theory of fuzzy sets and fuzzy logic.

Shafer-Dempster's Evidence Theory: A mathematical theory of evidence based on belief functions and plausible reasoning, which is used to combine separate pieces of information (evidence) to calculate the probability of an event. The theory was developed by Arthur P. Dempster and Glenn Shafer.

Theory of Endorsement: An approach to represent uncertainty proposed by Cohen, which is based on a qualitative theory of “endorsement.” According to Cohen, the records of the factors relating to one's certainty are called endorsements. Cohen's model of endorsement is based on the explicit recording of the justifications for a statement, normally requiring a complex data structure of information about the source. Therefore, this approach maintains the uncertainty. The justification is classified according to the type of evidence for a proposition, the possible actions required to solve the uncertainty of that evidence, and other related features.

Truth Maintenance System: A knowledge representation method for representing both beliefs and their dependencies. The name truth maintenance is due to the ability of these systems to restore consistency. There are two major truth maintenance systems: single-context and multi-context truth maintenance. In single context systems, consistency is maintained among all facts in memory (database). Multi-context systems allow consistency to be relevant to a subset of facts in memory (a context) according to the history of logical inference. This is achieved by tagging each fact or deduction with its logical history. Multi-agent truth maintenance systems perform truth maintenance across multiple memories, often located on different machines.

Many-Objective Evolutionary Optimisation

University of Exeter, UK

INTRODUCTION

Many-objective evolutionary optimisation is a recent research area that is concerned with the optimisation of problems consisting of a large number of performance criteria using evolutionary algorithms. Despite the tremendous development that multi-objective evolutionary algorithms (MOEAs) have undergone over the last decade, studies addressing problems consisting of a large number of objectives are still rare. The main reason is that these problems cause additional challenges with respect to low-dimensional ones. This chapter gives a detailed analysis of these challenges, provides a critical review of the traditional remedies and methods for the evolutionary optimisation of many-objective problems and presents the latest advances in this field.

BACKGROUND

There has been considerable recent interest in the optimisation of problems consisting of more than three performance criteria, realm that was coined many-objective optimisation by Farina and Amato (Farina, & Amato, 2002). To date, the vast majority of the literature has focused on two and three-dimensional problems (Deb, 2001). However, in recent years, the incorporation of multiple indicators into the problem formulation has clearly emerged as a prerequisite for a sound approach in many engineering applications (Coello Coello, Van Veldhuizen, & Lamont, 2002). Despite the tremendous development that MOEAs have undergone over the last decade, and their ample success in disparate applications, studies addressing high-dimensional real-life problems are still rare (Coello Coello, & Aguirre, 2002). The main reason is that

many-objective problems cause additional challenges with respect to low-dimensional ones:

If the dimensionality of the objective space increases, then in general, the dimensionality of the Pareto-optimal front also increases.

The number of points required to characterise the Pareto-optimal front increases exponentially with the number of objectives considered.

It is clear that these two features represent a hindrance for most of the population-based methods, including MOEAs. In fact, in order to provide a good approximation of a high-dimensional optimal Pareto front, this class of algorithms must evolve populations of solutions of considerable size. This has a profound impact on their performance, since evaluating each individual solution may be a time-consuming task. Using smaller populations would not be a viable option, at least for Pareto-based algorithms, given the progressive loss of selective pressure they experience as the number of objectives increases, with a consequent deterioration of performances, as it is theoretically shown in (Farina, & Amato, 2004) and empirically evidenced in (Deb, 2001, pages 404-405). In contrast to Pareto-based methods, traditional multi-objective optimisation approaches, which work by reducing the multi-objective problem into a series of parameterised single-objective ones that are solved in succession, are not affected by the curse of dimensionality. However, such strategies cause each optimisation to be executed independent to each other, thereby losing the implicit parallelism of population-based multi-objective algorithms.

The remainder of this chapter provides a detailed review of the methods proposed to address the first two

issues affecting many-objective evolutionary optimisation and discusses the latest advances in the field.

REMEDIAL MEASURES: STATE-OF-THE-ART

The possible remedies that have been proposed to address the issues arising in evolutionary many-objective optimisation can be broadly classified as follows:

- aggregation, goals and priorities
- conditions of optimality
- dimensionality reduction

In the next sub-sections we give an overview of each of these methods and review the approaches that have been so far proposed.

Aggregation, Goals and Priorities

This class of methods tries and overcome the difficulties described in the previous section through the decomposition of the original problem into a series of parameterised single-objective ones, that can then be solved by any classical or evolutionary algorithm.

Many aggregation-based methods have been presented so far and they are usually based on modifications of the weighted sum approach, such as the augmented Tchebycheff function, that are able to identify exposed solutions, and explore non-convex regions of the trade-off surface. However, the problem of selecting an effective strategy to vary weights or goals so that a representative approximation of the trade-off curve can be achieved is still unresolved.

The ϵ -constraint approach (Chankong, & Haimes, 1983), which is based on minimisation of one (the most preferred or primary) objective function while considering the other objectives as constraints bound by some allowable levels, was also used in the context of evolutionary computing. The main limitation of this approach is its computational cost and the lack of an effective strategy to vary bound levels (ϵ). Recently, Laumanns *et al.* (Laumanns, Thiele, & Zitzler, 2006) proposed a variant of the original approach where they developed a variation scheme based on the concept of ϵ -Pareto dominance (efficiency) (White, 1986) that adaptively generates constraint values, thus enabling the exhaustive exploration of the Pareto front, provided

the scheme is coupled with an exact single-objective optimiser. It must be pointed out however, that none of the methods described above has ever been thoroughly tested in the context of many-objective optimisation.

The Multiple Single Objective Pareto Sampling (MSOPS 1 & 2), an interesting hybridisation of the aggregation method with goal specification, was presented in (Hughes, 2003, Hughes, 2005). In the MSOPS, the selective pressure is not provided by Pareto ranking. Instead, a set of user defined target vectors is used in turn, in conjunction with an aggregation method, to evaluate the performance of each solution at every generation of a MOEA. The greater is the number of targets that a solution nears, the better its rank. The authors suggested two aggregation methods: the weighted min-max approach (implemented in MSOPS) and the Vector-Angle-Distance-Scaling (implemented in MSOPS 2). The results indicated with statistical significance that NSGA-II (Deb, Pratap, Agarwal, & Meyarivan, 2002), the Pareto-based MOEA used for comparative purposes, was outperformed on many objective problems. This was also recently confirmed by Wagner *et al.* in (Wagner, Beume, & Naujoks, 2007), where they benchmarked traditional MOEAs, aggregation-based methods and indicator-based methods on a up to 6-objective problems and suggested a more effective method to generate the target vectors.

Conditions of Optimality

Recently, great attention has been given to the role that conditions of optimality may play in the context of many-objective evolutionary optimisation when used to rank trial solutions during the selection stage of MOEA in alternative to, or conjunction with, Pareto efficiency. Farina *et al.* (Farina, & Amato, 2004) proposed the use of a fuzzy optimality condition, but did not provide a direct means to incorporate it into a MOEA. Köppen *et al.* (Köppen, Vincente-Garcia, & Nickolay, 2005) also suggested the fuzzification of the Pareto dominance relation, which was exploited within a generational elitist genetic algorithm on a synthetic MOP. The concept of *knee* (Deb, 2003), has also been exploited in the context of evolutionary many-objective optimisation. Simply stated, a knee is a portion of a Pareto surface where the marginal substitution rates are particularly high, i.e. a small improvement in one objective lead to a high deterioration of the others. A graphical representation is given in Figure 1. The idea

is that, with no prior information about the preference structures of the DM, the knee is likely to be the most interesting area. Branke *et al.* (Branke, Deb, Dierolf, & Osswald, 2004) developed two methodologies to detect solutions laying on knees, and incorporated them into the second stage (crowding measure) of the ranking procedure of NSGA-II. The first methodology consists in evaluating for each individual in a population the angle between itself and some neighbouring solutions and to use this value to favour solutions with higher angles, i.e. closer to the knee. The methodology, however, scales poorly with the number of objectives. The second strategy resorts to the expected marginal utility function to detect solutions close to the knee. This approach extends easily with the number of objectives; however, the sampling necessary to evaluate the expectation of the marginal utility function with a certain confidence may become expensive. Neither of these approaches has been tested on many-objective problems.

The concept of approximate optimal solutions has also been investigated to some extent in the context of evolutionary many-objective optimisation. In particular, ϵ -efficiency was considered to be potentially

effective to ease some of the difficulties associated with many-objective problems. A recent study by Wagner *et al.* (Wagner, Beume, & Naujoks, 2007) showed the excellent performance of ϵ -MOEA (Deb, Mohan, & Mishra, 2003) on a 6-objective instance of two synthetic test functions. A good review on the application of approximate conditions of optimality is given in (Burke, & Landa Silva, 2006), where the authors also compared the effect of using two relaxed forms of Pareto dominance as evaluation methods within two MOEAs.

Recently, di Pierro *et al.* (di Pierro, Khu, & Savić, 2007) proposed a ranking scheme based on Preference Ordering (Das, 1999), a condition of optimality that generalises Pareto efficiency, but it is more stringent, and tested it using NSGA-II as the optimisation shell on a suit of seven benchmark problems with up to eight objectives. Results indicated that the methodology proposed enhanced significantly the convergence properties of the standard NSGA-II algorithm on all the test problems. The strengths of this approach are its absence of parameters to tune and the fact that it showed very good performances across varying problem features; the drawbacks its computation runtime and

Figure 1. Simple Pareto front with a knee

the fact that its combination with diversity preserving mechanisms that favours extreme solutions may ingenerate too high of a selective pressure.

In (Sato, Aguirre, & Tanaka, 2007), Sato *et al.* introduced an approach to modify the Pareto dominance condition used within the selection stage of Pareto-based MOEAs, by which the area dominated by any given point is contracted or expanded according to a formula derived from the Sine theorem and the extent of the contraction/expansion is controlled by a constant factor. The results of a series of experiments performed using NSGA-II equipped with the contraction/expansion mechanism on 0/1 multi-objective knapsack problems showed substantially improved convergence and diversity performances compared to the standard NSGA-II algorithm. However, it was also shown that the optimal value for the contraction/expansion factor depends strongly on various problem features, and no indication was given to support a correct choice.

Most modern MOEAs rely on a two-stage ranking during the selection process. At the first stage the ranks are assigned according to some form of Pareto-based dominance relation; if ties exist, these are resolved resorting to mechanisms that favour a good distribution along the Pareto front of the solutions examined. It has now been acknowledged that this second stage of the ranking procedure may in fact be detrimental in case of many objectives, as it was shown in (Purshouse, & Fleming, 2003b) for the case of NSGA-II. Recent efforts have therefore focused on replacing diversity preserving mechanisms at this second stage with more effective ones. Koppen and Yoshida (Koppen, & Yoshida, 2007) proposed four secondary ranking assignments and tested them by replacing the crowding distance assignment within NSGA-II. The results indicated improved convergence in all cases compared to the standard NSGA-II. However, the authors did not report any result on the diversity performance of the algorithms.

Dimensionality Reduction Methods

The aim of this class of methods is usually to transform the objective space into a lower dimension representation, either one-off (prior to the optimisation) or iteratively (as the search progresses).

Deb and Saxena (Deb, & Saxena, 2006) developed a procedure based on principal component analysis

(PCA) for reducing the dimension of the problem to solve. The procedure consists in performing a series of optimisations using a state-of-the-art MOEA, each one focusing only on the objectives that PCA found explaining most of the variance on the basis of Pareto front obtained with the previous optimisation. Recently Saxena and Deb (Saxena, & Deb, 2007) extended their work and replaced PCA with two dimensionality reduction techniques, the correntropy PCA and a modified maximum variance unfolding that could also detect non-linear interactions in the objective space. The results indicated that the former method suffered to some extent from a difficult choice of the best kernel function to use, whereas for the latter, the authors performed a significant number of experiments to suggest bound values of the only free parameter of the procedure. It must be highlighted that these two studies are the only efforts that have challenged new algorithms on highly-dimensional test problems (up to 50 objectives).

In a recent study Brockhoff and Zitzler (Brockhoff, & Zitzler, 2006b) introduced the minimum objective subset problem (MOSS), which is concerned with the identification of the largest set of objectives that can be removed without altering the dominance structure of the problem (i.e. the set of Pareto optimal solutions obtained considering all the objectives or only the MOSS is the same), and developed an exact algorithm and a greedy heuristic to solve it. Subsequently (Brockhoff, & Zitzler, 2006a), they proposed a measure of variation for the dominance structure and extended the MOSS to allow for dimensionality reductions involving predefined thresholds of problem structure changes. However, they did not propose a mechanism to incorporate these algorithms within a MOEA.

Recently, the analysis of the relationships of interdependence between the objectives of an optimisation problem has been successfully exploited to devise effective reduction methods. Following the definitions of conflict, support or harmony, and independence proposed in (Carlsson, & Fuller, 1995), Purshouse and Fleming (Purshouse, & Fleming, 2003a) discussed the effects of these relationships in the context of many-objective evolutionary optimisation. In a later study Purshouse and Fleming (Purshouse, & Fleming, 2003c) also suggested, in the case of objectives independence, a divide-and-conquer algorithm based on objective space decomposition.

FUTURE TRENDS

As it appears from the discussion above, there is an increasing effort to develop strategies that are able to overcome the limitations of Pareto-based methods when solving problems with many objectives. Although promising results have been generally reported, most of the approaches presented are of an empirical nature, which makes it difficult to draw conclusions that can be generalised.

With the exception of dimensionality reduction techniques, the majority of the studies presented to date focus on mechanisms to improve the ranking of the solutions in the selection process. However, the analysis of these mechanisms is usually undertaken in isolation with respect to the other components of the algorithms. In our view, this is an important limitation that next generation algorithms will have to address, in particular, by undertaking the analysis of these mechanisms in relation with the variation operators.

Moreover, there has been little attention in trying to characterise the solutions that a given method (belonging to the first or second category identified in the previous section) favours, in relation to the properties of the problem being solved. Theoretical frameworks are therefore needed in order to analyse existing methods and develop more focused approaches. As it was pointed out by di Pierro in (di Pierro, 2006), where he provided a theoretical framework to analyse the effect of the Preference Ordering-based ranking procedure in relation to the interdependence relationships a problem, this approach enables predicting the effect of applying a given methodology to a particular problem with limited prior knowledge, which is certainly an advantage since the goal of developing powerful algorithms is to solve (often for the first time) real life problems.

CONCLUSIONS

In this chapter we have provided a comprehensive review of the state-of-the-art of evolutionary algorithms for the optimisation of many objective problems discussing limitations and strengths of the approaches described, and we have suggested future trends of research for a field that is gathering increasing momentum.

KEY TERMS

Evolutionary Algorithms: Solution methods inspired by the natural evolution process that evolve a population of solutions to an optimisation problem through iterative application of randomised processes of recombination and selection, until a termination criteria is met.

Many-Objective Problem: Problem consisting of more than 3-4 objectives to be concurrently maximised/minimised.

Pareto Front: Image of the Pareto Set onto the performance (objective) space.

Pareto Optimal Solution: Solution that is not dominated by any other feasible solution.

Pareto Set: Set of Pareto Optimal solutions.

Ranking Scheme: Scheme that assigns to each solution of a population a score that is a measure of its fitness relative to the other members of the same population.

Selective Pressure: The ratio between the number of expected selections of the best solution and the mean performing one.

Mapping Ontologies by Utilising Their Semantic Structure

Yi Zhao

Fernuniversitaet in Hagen, Germany

Wolfgang A. Halang

Fernuniversitaet in Hagen, Germany

INTRODUCTION

As a key factor to enable interoperability in the Semantic Web (Berners-Lee, Hendler & Lassila, 2001), ontologies are developed by different organisations at a large scale, also in overlapping areas. Therefore, ontology mapping has come into forth to achieve knowledge sharing and semantic integration in an environment where knowledge and information are represented by different underlying ontologies.

The ontology mapping problem can be defined as acquiring the relationships that hold between the entities of two ontologies. Mapping results can be used for various purposes such as schema/ontology integration, information retrieval, query mediation, or web service mapping.

In this article, a method to map concepts and properties between ontologies is presented. First, syntactic analysis is applied based on token strings, and then semantic analysis is executed according to WordNet (Fellbaum, 1999) and tree-like graphs representing the structures of ontologies. The experimental results exemplify that our algorithm finds mappings with high precision.

BACKGROUND

Borrowed from philosophy, ontology refers to a systematic account of what can exist or 'be' in the world. In the fields of artificial intelligence and knowledge representation, ontology refers to the construction of knowledge models that specify a set of concepts, their attributes, and the relationships between them. Ontologies are defined as "explicit conceptualisation(s) of a domain" (Gruber, 1993), and are seen as a key to realise the vision of the Semantic Web.

Ontology, as an important technique to represent

knowledge and information, allows to incorporate semantics into data to drastically enhance information exchange. The Semantic Web (Berners-Lee, Hendler & Lassila, 2001) is as a universal medium for data, information, and knowledge exchange. It suggests to annotate web resources with machine-processable metadata. With the rapid development of the Semantic Web, it is likely that the number of ontologies used will strongly increase over the next few years. By themselves, however, ontologies do not solve any interoperability problem. Ontology mapping (Ehrig, 2004) is, therefore, a key to exploit semantic interoperability of information and, thus, has been drawing great attention in the research community during recent years. This section introduces the basic concepts of information integration, ontologies, and ontology mapping.

Mismatches between ontologies are mainly caused by independent development of ontologies in different organisations. They become evident when trying to combine ontologies which describe partially overlapping domains. The mismatches between ontologies can broadly be distinguished into syntactic, semantic, and structural heterogeneity. Syntactic heterogeneity denotes differences in the language primitives used to specify ontologies, semantic heterogeneity denotes differences in the way domains are conceptualised and modelled, while structural heterogeneity denotes differences in information structuring.

There have been a number of previous works proposed so far on ontology mapping (Shvaiko, 2005, Noy, 2004, *Sabou, 2006, Su, 2006*). In (Madhavan, 2001), a hybrid similarity mapping algorithm has been introduced. The proposed measure integrates the linguistic and structural schema matching techniques. The matching is based primarily on schema element names, not considering their properties. LOM (Li, 2004) is a semi-automatic lexicon-based ontology-mapping tool that supports a human mapping engineer with a

first-cut comparison of ontological terms between the ontologies to be mapped. It decomposes multi-word terms into their word constituents except that it does not perform direct mapping between the words. The procedure associates the WordNet synset index numbers of the constituent words with ontological term. The two terms which have the largest number of common synsets are recorded and presented to the user.

MAIN FOCUS OF THE CHAPTER

Our current work tries to overcome the limitations mentioned above, and to improve precision of ontology mapping. The research goal is to develop a method and to evaluate results of ontology mappings.

In this article, we present a method to map ontologies synthesised of token-based syntactic analysis, and semantic analysis employing the WordNet (Fellbaum, 1999) thesaurus and tree-structured graphs. The algorithm is outlined and expressed in pseudo-code as listed in Figure 1. The promising results obtained from experiments indicate that our algorithm finds mappings

with high precision.

Syntax-Level Mapping Based on Tokenisation

Before employing syntactic mapping, a pre-processing is inevitable, which is called tokenisation. Here, ontologies are represented in the language OWL-DL¹. Therefore, all ontology terms are represented with OWL URI. For example, in ontology “beer”, an OWL Class ‘Ingredient’ is described by

“*[OWLClassImpl]* <http://www.purl.org/net/ontology/beer#Ingredient>”,

where “*[OWLClassImpl]*” implies OWL class, URL “<http://www.purl.org/net/ontology/beer>” addresses the provenance of the ontology, and ‘Ingredient’ is the class name. Tokenisation should first extract the valid ontology entities from OWL descriptions, which, in this example, is ‘Ingredient’.

Moreover, the labels of ontology entities (classes

and properties) are quite often defined with different representations by different organisations. For instance, representations may be with or without connector symbols, with upper or lower cases, etc., which renders it very complicated and hard to identify terms. Tokenisation means to parse names into tokens based on specific rules or symbols by customisable tokenisers using punctuation, upper case, special symbols, digits, etc. In this way, a class or property name can be tokenised into one or several token strings. For example, the term ‘Social_%26_Science’ can be tokenised as ‘Social’, ‘26’, and ‘Science’. Note that the terms can sometimes contain digits like date which is not neglectable.

For simplicity, we assume that all terms of ontology concepts (classes, properties) are described without abbreviations. The mapping process between different class and property names is then transformed to mapping between tokens.

We first check whether the original child nodes are equal ignoring case. Otherwise, the tokens are used instead to check whether they are equal. If not, the similarity measure based on the edit distance is adopted to calculate similarity. If the calculated similarity value is above a threshold σ (for example, 0.95), the compared nodes are considered to be similar. The process continues to deal with the next pair of nodes in the same way.

The edit distance formulated by Levenshtein (Levenshtein, 1966) and the string mapping method proposed by Maedche & Staab (Maedche & Staab, 2002) are employed here to calculate token similarity. The edit distance is a well-established method to weigh the difference between two strings. It measures the minimum number of token insertions, deletions, and substitutions required to transform one string into another using a dynamic programming algorithm. The string matching method is used to calculate token similarity based on Levenshtein’s edit distance:

$$Sim(X, Y) = \max(0, \frac{\min(|X|, |Y|) - ed(X, Y)}{\min(|X|, |Y|)}) \in [0, 1] \quad (1)$$

where X, Y are token strings, ‘ $|X|$ ’ is the length of X , ‘ $\min()$ ’ and ‘ $\max()$ ’ denotes the minimum/maximum value of two arguments, respectively, and ‘ $ed()$ ’ is the edit distance.

As the original ontology terms may have been to-

kenised into many sub-terms, i.e., tokens, it is necessary to separately calculate similarity between each pair of token strings. Assume that the number of tokens of the first term is m , n for the second term, and assume $m \geq n$, the total similarity measure according to Eq. (1) is:

$$Sim_{syn} = \omega_1 Sim_{orig} + \sum_{i=1}^m \sum_{j=1}^n \omega_{ij} Sim_{ij},$$

$$\omega_1 + \sum_{i=1}^m \sum_{j=1}^n \omega_{ij} = 1 \quad (2)$$

where Sim_{orig} is the similarity between the original strings, Sim_{ij} is the similarity between tokens i th and j th from two source terms, and ω_1, ω_{ij} are the weights for Sim_{orig} and Sim_{ij} . The sum of ω_{ij} and ω_1 are supposed to be 1. Given a predefined similarity threshold, if the acquired similarity value is greater than or equal to the threshold, then two tokens are considered similar, vice versa.

Semantic-Level Mapping Based on Ontology Structure

Semantic heterogeneity occurs when there is a disagreement about meaning, interpretation, or intended use of the same or related data. Semantic relations (Gahleitner, & Woess, 2004) are:

- different naming of the same content, i.e., synonyms,
- different abstraction levels: generic terms vs. more specific ones (name vs. first name and last name), hypernyms or hyponyms, and
- different structures about the same content (separate type vs. part of a type), i.e., meronyms.

In ontology mapping, WordNet is one of the most frequently used sources of background knowledge. Actually, it plays the role of an ‘intermediate’ to help finding semantic heterogeneity. The WordNet library can be accessed with the Java API JWN². It groups English words into sets of synonyms called synsets providing short, general definitions, and it records the various semantic relations between these synonym sets. The purpose is to produce a combination of dictionary and thesaurus that is more intuitively usable, and to support automatic text analysis and artificial intelligence applications. It is assumed that each sense in a

WordNet synset describes a concept. WordNet senses are related among themselves via synonym, hyponym, and hyperonym relations. Terms lexicalising the same concept (sense) are considered to be equivalent through the synonym relationship, while hypernyms, hyponyms, and meronyms are considered similar. With this rule, the original ontology terms and their relative token strings are first checked whether they have the same part of speech, i.e., noun, verb, adjective, adverb. The next step is to judge whether they are synonyms, hypernyms, hyponyms, or meronyms. Analogue to Eq. (2), for a pair of nodes a similarity value is calculated according to the weights of different similarity parts. If it exceeds a given threshold, the pair is considered to be similar.

If the above-mentioned syntactic and semantic WordNet mapping methods still could not find a mapping between two terms, another semantic-level method based on tree-structured graphs is applied.

As rendered with SWOOP³ (a hypermedia-inspired ontology browser and editor based on OWL ontologies, which supports renderers to obtain class/property hierarchy trees as well as definitions of and inferred facts on OWL classes and properties), ontology entities are represented by class/property hierarchy trees. From class hierarchy trees, tree-structured graphs are constructed. Based on the notion of structure graphs (Lian, 2004), a tree-structured graph (*ts-graph*) is defined as:

Definition 1. Given a tree of sets T , N the union of all sets in T , and E the set of edges in T , then *ts-g* (T) = (N , E) is called tree-structured graph of T ,

if it holds $(a, b) \in E$ if and only if a is a parent element of b ; a is called parent node, and b child node.

In building a *ts-graph*, breadth-first traversal is applied to traverse a tree hierarchy. To construct a *ts-graph*, we begin with the root node's first child node. All its child nodes and their relative parent nodes form edges as (parent node, child node) for the *ts-graph*. The process is repeated until the tree is completely traversed.

After the *ts-graphs* of two ontologies to be matched are built, the edge sets of both graphs are employed in the mapping process. The relative positions of a pair's (from two ontologies) nodes within their tree-structured graphs determines the semantic-level mapping between them. In Table 1 we summarise three types of relationships between edges characterising properties, child classes, and parent-and-child classes. By understanding these properties, we can derive that entities having the same properties are similar. This is not a rule always holding true, but it is a strong indicator for similarity.

Experimental Results

The implementation of our algorithm was written in Java. It relies on SWOOP for parsing OWL files. All tests were run on a standard PC (with Windows XP). Our test cases include ontologies "Baseball team", and "Russia" provided by the institute AIFB⁴.

To get an impression of the matchmaker's performance different measures have to be considered. There are various ways to measure how well retrieved information matches intended information. To evaluate

Table 1. Relationships between classes

| No. | Characteristic | Rules: Given two classes a and b |
|-----|--------------------------|--|
| R1 | Properties | If properties (data type property/object property \neq null) of a and b are similar, a and b are also similar. |
| R2 | Child classes | If all child classes of a and b are similar, a and b are also similar. |
| R3 | Parent-and-child classes | If parent class and one of the child classes of a and b are similar, a and b are also similar. |

Figure 2. Analysis of mapping results with ontologies Russia

the quality of mapping results, we use standard information-retrieval metrics: *Recall* (r), *Precision* (p), and *F-Measure* (Melnik & Rahm, 2002), where *Recall* is the ratio of the number of relevant entities retrieved to the total number of relevant entities, *Precision* is the ratio of the number of relevant records retrieved to the total number of irrelevant and relevant records retrieved, and

$$F\text{-Measure} = \frac{2rp}{r + p} \quad (3)$$

As shown in Figure 2, with the increase of the threshold, the mapping precision for “Russia” gets higher. The shortcoming of this method is its efficiency. Though we trade off efficiency to get more effective mapping results, our algorithm is still applicable to some offline web applications, like information filtering (Hanani, 2001) according to users’ profile.

FUTURE TRENDS

Currently, the results of similarity computations are provided in form of text documents. In order to present mapping results more reasonably and understandably, the objective of our future work is to treat the results of similarity computations as ontology. Another objective

of our future work is to address security problems connected to ontology mapping, such as trust management in the application of web services.

CONCLUSION

The overall research goal presented in this article is to develop a method for ontology mapping that combines syntactic analysis measuring the difference between tokens by the edit distance with semantic analysis based on WordNet as semantic relation and the similarity of structured graphs representing the ontologies being compared. Empirically we have shown that our synthesised mapping method works with relatively high precision.

KEY TERMS

Ontology: As a means to conceptualise and structure knowledge, ontologies are seen as the key to realise the vision of the semantic web

Ontology Mapping: Ontology mapping is required to achieve knowledge sharing and semantic integration in an environment with different underlying ontologies.

Precision: The ratio of the number of relevant records retrieved to the total number of irrelevant and relevant records retrieved.

Recall: The ratio of the number of relevant entities retrieved to the total number of relevant entities.

Semantic Web: Envisioned by Tim Berners-Lee, the semantic web is as a universal medium for data, information, and knowledge exchange. It suggests to annotate web resources with machine-processable metadata.

Similarity Measure: A method used to calculate the degree of similarity between mapping sources.

Tokenisation: Tokenisation extracts the valid ontology entities from OWL descriptions.

Tree-Structured Graph: A graphical structure to represent a tree with nodes and a hierarchy of its edges.

Mathematical Modeling of Artificial Neural Networks

Radu Mutihac

University of Bucharest, Romania

INTRODUCTION

Models and algorithms have been designed to mimic information processing and knowledge acquisition of the human brain generically called artificial or formal neural networks (ANNs), parallel distributed processing (PDP), neuromorphic or connectionist models. The term network is common today: computer networks exist, communications are referred to as networking, corporations and markets are structured in networks. The concept of ANN was initially coined as a hopeful vision of anticipating artificial intelligence (AI) synthesis by emulating the biological brain.

ANNs are alternative means to symbol programming aiming to implement neural-inspired concepts in AI environments (neural computing) (Hertz, Krogh, & Palmer, 1991), whereas cognitive systems attempt to mimic the actual biological nervous systems (computational neuroscience). All conceivable neuromorphic models lie in between and supposed to be a simplified but meaningful representation of some reality. In order to establish a unifying theory of neural computing and computational neuroscience, mathematical theories should be developed along with specific methods of analysis (Amari, 1989) (Amit, 1990). The following outlines a tentatively mathematical-closed framework in neural modeling.

BACKGROUND

ANNs may be regarded as dynamic systems (discrete or continuous), whose states are the activity patterns, and whose controls are the synaptic weights, which control the flux of information between the processing units (adaptive systems controlled by synaptic matrices). ANNs are parallel in the sense that most neurons process data at the same time. This process can be synchronous, if the processing time of an input neuron is the same for all units of the net, and

asynchronous otherwise. Synchronous models may be regarded as discrete models. As biological neurons are asynchronous, they require a continuous time treatment by differential equations.

Alternatively, ANNs can recognize the state of environment and act on the environment to adapt to given viability constraints (cognitive systems controlled by conceptual controls). Knowledge is stored in conceptual controls rather than encoded in synaptic matrices, whereas learning rules describe the dynamics of conceptual controls in terms of state evolution in adapting to viability constraints.

The concept of paradigm referring to ANNs typically comprises a description of the form and functions of the processing unit (neuron, node), a network topology that describes the pattern of weighted interconnections among the units, and a learning rule to establish the values of the weights (Domany, 1988). Although paradigms differ in details, they still have a common subset of selected attributes (Jansson, 1991) like simple processing units, high connectivity, parallel processing, nonlinear transfer function, feedback paths, non-algorithmic data processing, self-organization, adaptation (learning) and fault tolerance. Some extra features might be: generalization, useful outputs from fuzzy inputs, energy saving, and potential overall high speed operation.

The digital paradigm dominating computer science assumes that information must be digitized to avoid noise interference and signal degradation. In contrast, a neuron is highly analog in the sense that its computations are based on spatiotemporal integrative processes of smoothly varying ion currents at the trigger zone rather than on bits. Yet neural systems are highly efficient and reliable information processors.

Memory and Learning

The specificity of neural processes consists in their distributive and collective nature. The phenomenon

by biological neural networks (NNs) are changing in response to extrinsic stimuli is called self-organization. The flexible nature of the human brain, represented by self-organization, seems to be responsible for the learning function which is specific to living organisms. Essentially, learning is an adaptive self-organizing process. From the training assistance point of view, there are supervised and unsupervised neural classifiers. Supervised classifiers seek to characterize predefined classes by defining measures that maximize in-class similarity and out-class dissimilarity. Supervision may be conducted either by direct comparison of output with the desired target and estimating error, or by specifying whether the output is correct or not (reinforcement learning). The measure of success in both cases is given by the ability to recover the original classes for similar but not identical input data. Unsupervised classifiers seek similarity measures without any predefined classes performing cluster analysis or vector quantization. Neural classifiers organize themselves according to their initial state, types and frequency of the presented patterns, and correlations in the input patterns by setting up some criteria for classification (Fukushima, 1975) reflecting causal mechanisms. There is no general agreement on the measure of their success since likelihood optimization always tends to favor single instance classes.

Classification as performed by ANNs has essentially a dual interpretation reflected by machine learning too. It could mean either the assignment of input patterns to predefined classes, or the construction of new classes from a previously undifferentiated instance set (Stutz & Cheesman, 1994). However, the assignment of instances to predefined classes can produce either the class that best represents the input pattern as in the classical decision theory, or the classifier can be used as a content-addressable or associative memory, where the class representative is desired and the input pattern is used to determine which exemplar to produce. While the first task assumes that inputs were corrupted by some processes, the second one deals with incomplete input patterns when retrieval of full information is the goal. Most neural classifiers do not require simultaneous availability of all training data and frequently yield error rates comparable to Bayesian methods without needing prior information. An efficient memory might store and retrieve many patterns, so its dynamics must allow for as many states of activity which are stable against small perturbations as possible. Several ap-

proaches dealing with uncertainty such as fuzzy logic, probabilistic, hyperplane, kernel, and exemplar-based classifiers can be incorporated into ANN classifiers in applications where only few data are available (Ng & Lippmann, 1991).

The capacity of analog neural systems to operate in unpredictable environments depends on their ability to represent information in context. The context of a signal may be some complex collections of neural patterns, including those that constitute learning. The interplay of context and adaptation is a fundamental principle of the neural paradigm. As only variations and differences convey information, permanent change is a necessity for neural systems rather than a source of difficulty as it is for digital systems.

MATHEMATICAL FRAMEWORK OF NEURONS AND ANNS MODELING

An approach to investigate neural systems in a general frame is the mean field theory (Cooper & Scofield, 1988) from statistical physics suited for highly interconnected systems as cortical regions are. However, there is a big gap between the formal model level of description in associative memory levels and the complexity of neural dynamics in biological nets. Neural modeling need no information concerning correlations of input data, rather nonlinear processing units and a sufficiently large number of variable parameters ensure the flexibility to adapt to any relationship between input and output data. Models can be altered externally, by adopting a different axiomatic structure, and internally, by revealing new inside structural or functional relationships. Ranking several neuromorphic models is ultimately carried out based on some measure of performance.

Neuron Modeling

Central problems in any artificial system designed to mimic NNs arise from (i) biological features to be preserved, (ii) connectivity matrix of the processing units, whose size increases with the square of their number, and (iii) processing time, which has to be independent of the network size. Biologically realistic models of neurons might minimally include:

- Continuous-valued transfer functions (graded response), as many neurons respond to their

input in a continuous way, though the nonlinear relationship between the input and the output of cells is a universal feature;

- Nonlinear summation of the inputs and significant logical processing performed along the dendritic tree;
- Sequences of pulses as output, rather than a simple output level. A single state variable y_j representing the firing rate, even if continuous, ignores much information (e.g., pulse phase) that might be encoded in pulse sequences. However, there is no relevant evidence that phase plays a significant role in most neuronal circuits;
- Asynchronous updating and variable delay of data processing, that is, the time unit elapsing per processing step, $t \rightarrow t + 1$, is variable among neurons;
- Variability of synaptic strengths caused by the amount of transmitter substance released at a chemical synapse, which may vary unpredictably. This effect is partially modeled by stochastic generalization of the binary neural models dynamics.

Most neuromimetic models are based on the McCulloch and Pitts (1943) neuron as a binary threshold unit:

$$y_j(t+1) = \Theta \left(\sum_{i=1}^N w_i^j x_i(t) - \theta_j \right) \quad (1)$$

where y_j represents the state of neuron j (either 1 or 0) in response to input signals $\{x_i\}$, θ_j stands for a certain threshold characteristic of each neuron j , time t is considered discrete, with one time unit elapsing per processing step, and Θ is the unit step (Heaviside) function:

$$\Theta(x) = \begin{cases} 1, & x \geq 0 \\ 0, & x < 0 \end{cases} \quad (2)$$

The weights, w_i^j , $1 \leq i \leq N$, represent the strengths of the synapses connecting neuron i to neuron j , and may be positive (excitatory) or negative (inhibitory). The weighted sum

Figure 1. Typical sigmoid transfer functions

$$\sum_{i=1}^N w_i^j x_i(t)$$

of the inputs presented at time t to unit j must reach or exceed the threshold θ_j for the neuron j to fire. Though extremely simplified, a synchronous assembly of such formal neurons is theoretically capable of universal computation (Welstead, 1994) for suitable chosen weights $\{w_i^j\}_{i,j}$, i.e., it may perform computations that conventional computers do, yet not necessarily so rapidly or conveniently.

A general expression that includes some of the above features derived from the digital model (1) is:

$$y_j = f_j \left(\sum_{i=1}^N w_i^j x_i - \theta_j \right) \quad (3)$$

where y_j is the continuous-valued state (activation) of unit j and f_j is a general transfer function. Threshold nodes are required for universal approximation and the activation function ought to be nonlinear with bounded output (Fig. 1). The neurons are updated asynchronously in random order at random times.

Mathematical Methods for ANNs Modeling

Several neural models and parallel information processing systems inspired by brain mechanisms were proposed. Almost all practical applications were achieved by simulation on conventional digital computers (von Neumann), so the real parallel processing advantages and massive unit densities hoped for were lost. Mathematical methods approaching various types of ANNs in a unified way and results from linear and nonlinear control systems used to obtain learning algorithms could be grouped in four categories:

1. Tensor products and pseudo-inverses of linear operators, which represent the specific structural connectionism and provide a mathematical explanation of the Hebbian nature of many learning algorithms (Hebb, 1949). This is due to the fact that derivatives of a wide class of nonlinear maps defined on spaces of synaptic matrices are tensor products and because the pseudo-inverse of a tensor product of linear operators is the tensor product of their pseudo-inverses;
2. Convex and nonsmooth analysis is particularly suited to nonlinear networks in proving the convergence of two main types of learning rules. The first class consists of algorithms derived from gradient methods and includes the backpropagation update rule, whereas the second class deals with algorithms based on Newton's method;
3. Control and viability theory (Aubin, 1991), which deals with neural systems that learn viable solutions as control systems satisfying given viability (state) constraints. The purpose is to derive algorithms of control systems emulated by ANNs with feedback regulation. Three classes of learning rules are envisaged: (i) external learning rules based on gradient methods of optimization problems involving nonsmooth functions, (ii) internal learning rules based on the viability theory, and (iii) uniform algorithms;
4. Probability theory and Bayesian statistics. Bayesian statistics and neural modeling may seem extremes of the data-modeling spectrum. ANNs are nonlinear parallel computational devices and their training by example to solve prediction and classification problems is quite a purpose-specific procedure. Contrarily, Bayesian statistics is heavily based on coherent inference and clearly defined axioms. Yet both approaches aim to create models in good accordance with the data. ANNs can be interpreted as more flexible versions of traditional regression techniques in the sense of capturing regularities in the data that the linear models are not able to handle. However, over-flexible ANNs may discover non-existent correlations in the data. Bayesian inference provides means to infer how flexible a model is warranted by the data and suppresses the tendency to assess spurious structure in the data by incorporating the Occam's razor that sets the preference for simpler models if they compete to come out with the same result. Learning in ANNs is interpreted as inference on the most probable parameters for a model, given the training data. The search in the model space can also be treated as an inference problem of relative probability for alternative models, given the data. Bayesian inference for ANNs can be implemented numerically by deterministic methods involving Gaussian approximations (MacKay, 1992), or by Monte Carlo methods (Neal, 1996).

Let N formal neurons link, directly for one-layer networks and indirectly for multi-layered ones, an input space X of signals to an output space Y . The state space of the system is the product $X \times Y$ of the input-output pairs (x,y) , which are generically called patterns or configurations in pattern recognition (PR), data analysis, and classification problems. When $X = Y$ and the input of the patterns coincide with the outputs, (x,y) , $x = y$, the system is called autoassociative; if the input and output patterns are different, (x,y) $y \neq x$, then the system is heteroassociative. Among all possible input-output patterns, a subset $K \subset X \times Y$ is chosen as training set. Most often, the input and output spaces are finite dimensional linear spaces: $X = \mathbb{R}^N$ and $Y = \mathbb{R}^M$, whereas the input signals may obey some state constraints:

- Real numbers for fuzzy applications, preferably in the intervals $[0,1]$ or $[-1, +1]$;
- Binary numbers that belong to $\{0, 1\}$;
- Bipolar numbers that belong to $\{-1, +1\}$.

If neurons are labeled by $j = 1, 2, \dots, N$, then let $P(N)$ of cardinal 2^N denote the family of subsets of neurons called conjuncts (or coalitions) of neurons. Any con-

nection links a postsynaptic neuron j to conjuncts $S \subset P(N)$ of presynaptic neurons. Each conjunct S preprocesses (or gates) the afferent signals $\{x_i\}_i$ produced by the presynaptic neurons through a function:

$$\{x_i\}_{i=1,2,\dots,N} \xrightarrow{\varphi_S} \varphi_S(x) \quad (4)$$

If conjuncts are reduced to individual neurons $S = \{i\}$, then the role of control is played by the synaptic matrix:

$$\mathbf{W} = \left\| w_j^S \right\|_{\substack{S \subset P(N) \\ j=1,2,\dots,N}} \quad (5)$$

where w_j^S represents the entries from S to neuron j . The modulus of the synaptic weight w_j^S represents the strength and it gives the nature of the connection from conjunct S to the formal neuron j , counted positively if the synapse is excitatory, and negatively if it is inhibitory. Accordingly, the neuron j receives the signal

$$\sum_{S \subset P(N)} w_j^S \varphi_S(x)$$

Figure 2. Conjuncts of neurons $\{2,3\}$ and $\{4,5,6\}$ gate the inputs to neuron 1

(Fig. 2), which determines its state of activity. Hence the propagation rule that characterize the network dynamics is:

$$y_j = f_j \left(\{w_j^s, \varphi_s(x)\}_{s \in P(N)} \right) \quad (6)$$

for synchronous neurons (discrete dynamical system), and:

$$x_j'(t) = f_j \left(\{w_j^s(t), \varphi_s(x, t)\}_{s \in P(N)} \right) \quad (7)$$

for asynchronous neurons (continuous dynamical system), where in most cases:

$$f_j \left(\{w_j^s, \varphi_s(x)\}_{s \in P(N)} \right) = g_j \left(\sum_{s \in P(N)} w_j^s \varphi_s(x) \right) \quad (8)$$

Here g_j integrates the afferent signals $\{w_j^s \varphi_s(x)\}$ sent to the neuron j by the afferent neurons through their outputs $\{x_i\}_i$, preprocessed by the conjunct S , and delivered to neuron j via the weight w_j^S . Usually, the synaptic weights $w_j^S = 0$ when $j \in S$, whereas $w_j^S \neq 0$ when $j \in S$ is associated with autoexcitation. However, when $S = \{j\}$, $S \neq \{i\}$, and $w_j^S = 0$, then the loss term $g_j(0, 0, \dots, w_j^i \varphi_j(x), 0, \dots, 0)$ represents some kind of forgetting like decaying frequency while the neuron in question j is not excited by the others.

Several neural systems can be expressed within this framework (Aubin, 1991).

1. Associative memories are defined by the lack of preprocessing, that is,

$$\varphi_s(x) = 0 \text{ if } |S| > 1 \text{ or } \varphi_s(x) = x_i \text{ if } S = \{i\},$$

then:

$$y_j = \sum_{i=1}^N w_j^i x_i + c_j \quad (9)$$

where $|S|$ stands for the number of elements in conjunct S .

2. Associative memories with gates are defined by preprocessing and g_j affine:

$$y_j = \sum_{i=1}^N w_j^i x_i + c_j \quad (10)$$

Boolean associative memories correspond to

$$X = \mathbb{R}^N, \quad Y = \mathbb{R}, \quad K = \{0, 1\}^N \times \{0, 1\},$$

and fuzzy associative memories to

$$X = \mathbb{R}^N, \quad Y = \mathbb{R}, \quad K = [0, 1]^N \times [0, 1],$$

hence:

$$y = \sum_{s \in P(N)} w^s \prod_{i \in S} x_i^{\frac{1}{|S|}} \quad (11)$$

3. Nonlinear automata are defined by various forms of g_j :

$$f_j(x, W) = g_j \left(\sum_{s \in P(N)} w_j^s \varphi_s(x) \right) \quad (12)$$

When appropriate, thresholds $\theta \in Y$ may be integrated in the processing function g :

$$g(z) = h(z - \theta) \quad (13)$$

If the threshold is part of the controls to be adjusted during training, it may be incorporated as an entry of an extended synaptic matrix:

$$\hat{W} = \left\| \hat{w}_{ij} \right\|_{\substack{i=1,2,\dots,N \\ j=0,1,\dots,M}} \in L(\mathbb{R} \times X, Y),$$

$$\hat{w}_{ij} = \begin{cases} w_{ij} & \text{for } i = 1, 2, \dots, N ; j = 1, 2, \dots, M \\ \theta_i & \text{for } i = 1, 2, \dots, N ; j = 0 \end{cases} \quad (14)$$

Particularly simple is the perceptron:

$$X = \mathbb{R}^N, \quad Y = \mathbb{R}, \quad \theta \in Y,$$

$$\varphi_s(x) = 0$$

if $|S| > 1$, then:

$$y = \begin{cases} 0 & \text{if } \sum_{i=1}^N w^i x_i < \theta \\ 1 & \text{if } \sum_{i=1}^N w^i x_i \geq \theta \end{cases} \quad (15)$$

FUTURE TRENDS

Some promising neural-inspired approaches to feature extraction and clustering were also proposed (Mao & Jain, 1995), which are adaptive online and may exhibit additional desirable properties such as robustness against outliers (Xu & Yuille, 1995) as compared to more traditional feature extraction methods.

The connection between Bayesian inference and neural models gives new perspectives to the assumptions and approximations made on ANNs and algorithms when used as associative memories. Advances in neural modeling and training algorithm design addressed dynamic range and sensitivity problems encountered by large analog systems, along with fast evolution in VLSI implementation techniques, could lead to practical real-time systems derived from the topology and parallel distributed processing performed by biological NNs.

CONCLUSION

Though ANNs are able to perform a large variety of tasks, the problems handled practically could be loosely divided into four basic types (Zupan & Gasteiger, 1994): auto- or hetero-association, classification, mapping (Kohonen, 1982), and modeling.

In neural classifiers, the set of examples used for training should necessarily come from the same (possibly unknown) distribution as the set used for testing the networks, in order to provide reliable generalization in classifying unknown patterns. Valid results are only produced if the training examples are adequately selected and their number is comparable to the number of effective parameters in the net. Quite a few classes of learning algorithms have the convergence guaranteed; moreover, they require substantial computational resources.

Generally, ANNs are used as parts of larger systems employed as preprocessing or labeling/interpretation subsystems. In many cases, the flexibility and non-algorithmic processing of ANNs surpass their incon-

veniences and make them suitable for modeling rather complex systems involving plenty of information.

KEY TERMS

Artificial Neural Networks (ANNs): Highly parallel networks of interconnected simple computational elements (cells, nodes, neurons, units), which mimic biological neural network.

Complex Systems: Systems made of several interconnected simple parts which altogether exhibit a high degree of complexity from each emerges a higher order behaviour.

Emergence: Modalities in which complex systems like ANNs and patterns come out of a multiplicity of relatively simple interactions.

Learning (Training) Rule: Iterative process of updating the weights from cases (instances) repeatedly presented as input. Learning (adaptation) is essential in PR where the training data set is limited and new environments are continuously encountered.

Paradigm of ANNs: Set of (i) pre-processing units' form and functions, (ii) network topology that describes the number of layers, the number of nodes per layer, and the pattern of weighted interconnections among the nodes, and (iii) learning (training) rule that specifies the way weights should be adapted during use in order to improve network performance.

Relaxation: Process by which ANNs minimize an objective function using semi- or non-parametric methods to iteratively updating the weights.

Robustness: Property of ANNs to accomplish reliable its tasks when handling incomplete and/or corrupted data. Moreover, the results should be consistent even if some part of the network is damaged.

Self-Organization Principle: A process in which the internal organization of a system that continually interacts with its environment increases in complexity without being driven by an outside source. Self-organizing systems typically exhibit emergent properties.

Microarray Information and Data Integration Using SAMIDI

INTRODUCTION

Technological advances in high-throughput techniques and efficient data gathering methods, coupled computational biology efforts, have resulted in a vast amount of life science data often available in distributed and heterogeneous repositories. These repositories contain information such as sequence and structure data, annotations for biological data, results of complex computations, genetic sequences and multiple bio-datasets. However, the heterogeneity of these data, have created a need for research in resource integration and platform independent processing of investigative queries, involving heterogeneous data sources.

When processing huge amounts of data, information integration is one of the most critical issues, because it's crucial to preserve the intrinsic semantics of all the merged data sources. This integration would allow the proper organization of data, fostering the analysis and access the information to accomplish critical tasks, such as the processing of micro-array data to study protein function and medical researches in making detailed studies of protein structures to facilitate drug design (Ignacimuthu, 2005). Furthermore, DNA micro-array research community urgently requires technology to allow up-to-date micro-array data information to be found, accessed and delivered in a secure framework (Sinnot, 2007).

Several research disciplines, such as Bioinformatics, where information integration is critical, could benefit

from harnessing the potential of a new approach: the Semantic Web (SW). The SW term was coined by Berners-Lee, Hendler and Lassila (2001) to describe the evolution of a Web that consisted of largely documents for humans to read towards a new paradigm that included data and information for computers to manipulate. The SW is about adding machine-understandable and machine-processable metadata to Web resource through its key-enabling technology: ontologies (Fensel, 2002). Ontologies are a formal explicit and shared specification of a conceptualization. The SW was conceived as a way to solve the need for data integration on the Web.

This article expounds SAMIDI, a Semantics-based Architecture for Micro-array Information and Data Integration. The most remarkable innovation offered by SAMIDI is the use of semantics as a tool for leveraging different vocabularies and terminologies and foster integration. SAMIDI is composed of a methodology for the unification of heterogeneous data sources from the analysis of the requirements of the unified data set and a software architecture.

BACKGROUND

This section introduces Bioinformatics and its need to process massive amounts of data; the benefit of the integration of the existing data sources of biological information and semantics, a tool for integration.

Bioinformatics

The term Bioinformatics was coined by Hwa Lim in the late 1980s, and later popularized through its association with the human genome project (Goodman, 2002). Bioinformatics is the application of information science and technologies for the management of biological data (Denn & MacMullen, 2002) and it describes any use of computers to store, compare, retrieve, analyze or predict the composition of the structure of biomolecules (Segall & Zhang, 2006). Research on Biology requires Bioinformatics to manipulate and discover new biological knowledge at several levels of increasing complexity. Biological data are produced through high-throughput methods (Vyas & Summers, 2005), which means that they have to be represented and stored in different formats, such as micro-arrays.

Micro-Array Data Sources

A DNA micro-array is a collection of microscopic DNA spots attached to a solid surface forming an array for the purpose of expression profiling, which monitors expression levels for thousands of genes simultaneously. Those features are read by a scanner that measures the level of activation, and the data is downloaded onto a computer for subsequent analysis (Cohen, 2005). Micro-arrays allow investigating millions of genes simultaneously (Segall & Zhang, 2006). A biological experiment may require hundreds of micro-arrays, where a single micro-array generates up to millions of fragments of data (Murphy, 2002). This fact makes data analysis and management a major challenge for gene expression studies using micro-arrays (Xu, Maresh, Giardina & Pincus, 2004).

The need to manage data generated from Bioinformatics is crucial. Understanding biological processes necessitates access to collections of potentially distributed, separately owned and managed biological data sets (Sinnott, 2007). These data sources reside in different storages, hardware platforms, data base management systems, data models and data languages (Chen, Prompormote & Maire, 2006), which makes impossible their integration. To make things worse, this incompatibility is not limited to the use of different data technologies, but also because of its incompatibility in terms of semantics. This heterogeneity can be of two sorts: *syntactic* and *semantic* (Verschelde, Dos Santos, Deray, Smith & Ceusters, 2004). Syntactic

heterogeneity refers to differences in data models and data languages and can be easily resolved. Semantic heterogeneity refers to the underlying meanings of the data represented. It gives origin to naming conflicts and structural conflicts.

This incompatibility, and the necessity of sharing and aggregating information among the existing micro-array data sources leads researchers to seek for data integration.

Micro-Array Data Integration

Data analysis and management represent a major challenge for gene expression studies using micro-arrays (Xu, Maresh, Giardina & Pincus, 2004). Micro-array technology is still rather new and standards are not established (Murphy, 2002). This lack of standardization impedes micro-array data exchange. However, several projects have been started with a common goal: facilitate the exchange and analysis of micro-array data. MIAME (Minimum Information About Micro-array Experiment) is an XML based standard for the description of micro-array experiments. It's gaining importance because it is required by numerous journals for the submission of articles providing micro-array experiments results. The purpose of MIAME is to define the core information needed for the description of an array based gene expression monitoring experiment. MAGE (Micro-Array Gene Expression) is a standard micro-array data model and exchange format that is able to capture information specified by MIAME.

Integration and Semantics

The ambiguity of terms, both within and between different databases and terminologies, makes integrating bioinformatics data task highly error prone (Verschelde *et al.*, 2004). Converting all this information into a common data format will likely never be achieved and, therefore, the solution to the effective information management problem will necessarily go through the establishment of a common understanding. At this point is where semantics comes into play, bridging nomenclature and terminological inconsistencies to comprehend underlying meaning in a unified manner. The key elements that enable semantic interoperability are ontologies; semantic models of the data and they interweave human understanding of symbols with their machine processability (Della Valle, Cerizza, Bicer,

Kabak, Laleci & Lausen, 2005). Ontologies allow to organise terms used in heterogeneous data sources according to their semantic relationships so that heterogeneous data fragments can be mapped into a consistent frame of reference (Buttler, Coleman, Critchlow, Fileto, Han, Pu, Rocco & Xiong, 2002).

Applying semantics allows capturing the meaning of data one single time. Without semantics, each data element will have to be interpreted several times from its design and implementation until its use, facilitating error raise. Finally, semantics allows turning a great set of data sources into an integrated, coherent and unique body of information. The architecture of the information itself contains a record to keep the meaning and locate each data asset, enabling the automation of overlapping and redundancy analysis.

One of the most important contributions of ontology to the unification of biological data schemas is the MGED (Microarray Gene Expression Data) ontology (Whetzel, Parkinson, Causton, Fan, Fostel, Fragoso, Game, Heiskanen, Morrison, & Rocca-Serra, 2006) that was prompted by the heterogeneity among MI-AME and MAGE formats. MGED is a conceptual model for micro-array experiments that establishes concepts, definitions, terms and resources for standardized description of a micro-array experiment in support of MAGE. MGED has been accepted as a unifying terminology by the micro-array research community, which makes it a perfect candidate for becoming a universal understanding model.

THE SAMIDI APPROACH

SAMIDI is both a methodology to allow the conversion of a set of micro-array data sources into a unified representation of the information they include, and a software architecture. A general overview of SAMIDI is depicted in Figure 1.

The Unifying Information Model (UIM)

It brings together all the physical data schemas related to the data sources to be integrated. It doesn't replicate any of the data models, but is built to represent an agreed-upon scientific view and vocabulary which will be the foundation to understand the data. The UIM might capture the major concepts present in each schema for, after applying a semantic mapping, relate the physical schemas of the various data sources to the Model itself. Thus, the semantic mapping encapsulates the meaning of the data, taking into account the agreed-upon terminology. The UIM also provides the basis for the creation of new data assets, assuring they are consistent with the underlying schemas, and serves as a reliable reference for understanding the interrelationship between seemingly unrelated sources and for automatically planning the translation of data elements between them.

Figure 1. SAMIDI

The Semantic Information Management Methodology (SIMM)

Its aim is to fill the existent gap between the fragmented information scenario represented by the set of micro-array data sources to be integrated and the required semantic data integration. The methodology is arranged in such a way that each of the phases generates a substantial added value itself, while concurrently progressing towards the full semantic integration. Next, the different stages of the methodology (Figure 2) are detailed:

1. *Capture Requirements*: The project scope is established by surveying the relevant data sources to be integrated and determining the information requirements of the aimed information model.
2. *Collect Metadata*: Data assets are classified and catalogued while the relevant (according to the organization's use of data) metadata are collected.
3. *Build UIM*: The structure of the UIM is determined by representing the desired business world-view, a comprehensive and consistent vocabulary and a set of business rules.
4. *Rationalize data semantics*: The meaning of the represented data is mapped into the UIM.
5. *Deploy*: The UIM, the metadata and the semantics are shared among the intended stakeholders and customized to fulfill their needs.
6. *Exploit*: Business processes are created, ensuring that the architecture has achieved the data management, data integration and data quality objectives.

The effective application of the SIMM requires a support information system. Key components of the supporting system should include:

- A repository for storing the collected metadata on data assets, schemas and models.
- A set of semantic tools for integrated ontology modeling for the creation of the UIM and the semantic mapping of the data schemas to the model.
- The standard business terminology stemmed from the UIM should be used across the supporting system.
- Data management capabilities of the system should include authoring and editing the information model; discovering data assets for any particular business concept; creating qualitative and quantitative reports about data assets; testing and simulating the performance of the UIM and impact analyzing in support of change.
- The system should fully support data integration by automatically generating code for queries and translation scripts between mapped schemas harnessing the common understanding acquired from the data semantics.
- Data quality should be approached by supporting the identification and decommissioning of redundant data assets, comparison mechanisms for ensuring consistency among semantically dissimilar data, and validation/cleansing of individual sources against the central repository of rules.
- The system should allow bi-directional communication with other systems for exchanging metadata and models by means of adaptors and

Figure 2. SIMM

standards such as XML Metadata Interchange standard. Similarly, the system should be able to collect metadata and other data assets from relational databases or other kind of repositories.

- Capability of active data integration. The system should have a Run-Time interface for the automatic generation and exporting of queries, translation scripts, schemas and cleansing scripts.
- The user interface should provide a rich thick-client for power users in the data management group.
- The system should include a transversal platform supporting shared functionalities such as version control, collaboration tools, access control and configuration for all metadata and active content in the system.

The SAMIDI Software Architecture

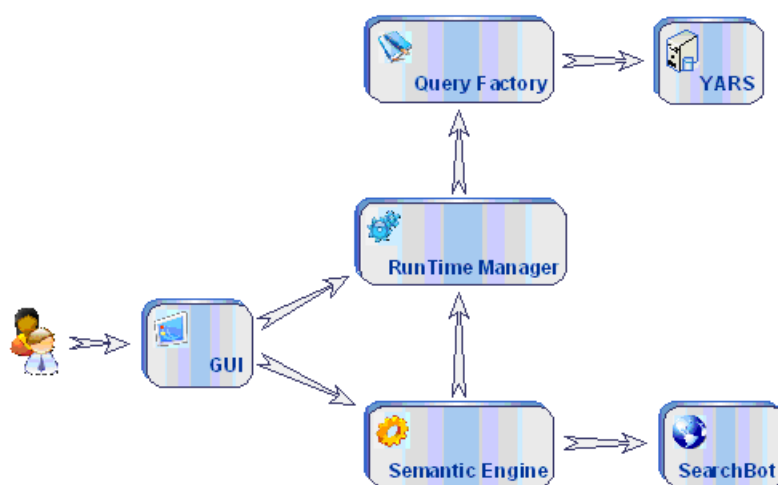

A detailed description of the components comprised in the SAMIDI software architecture (see Figure 3) is presented now:

- SearchBot: Software agent whose mission is to perform a methodical, systematic and automatic browsing of the integrated information sources.
- Semantic Engine: Integrated set of tools for the semantic mapping of the data schemas to the

UIM using the MGED ontology. It will provide a semi-automatic mechanism for the mapping of schemas and concepts or categories in the UIM so as to lessen the workload of a process that will require human intervention. Fully automatic mapping has been discarded since it is regarded as not recommendable due to semantic incompatibilities and ambiguities among the different schemas and data formats. The objective of the Semantic Engine is to bridge the gap between cost-efficient machine-learning mapping techniques and pure human interaction.

- YARS: The YARS (Yet Another RDF Store) (Harth & Decker, 2005) system is a semantic data store that allows semantic querying and offers a higher abstraction layer to enable fast storage and retrieval of large amounts of metadata descriptions while keeping a small footprint and a lightweight architecture approach.
- GUI: Enables user-system interaction. It collects requests following certain search criteria, transfers the appropriate commands to and displays the results provided as a response from the RunTime Manager.
- Query Factory: Build queries into YARS storage systems using a query language. The semantics of the query are defined by an interpretation of the most suitable results of the query instead of

Figure 3. SAMIDI architecture

- strictly rendering a formal syntax. YARS stores RDF triples, and the query factory, for pragmatic reasons, implements SPARQL Query Language for RDF (Prud'hommeaux & Seaborne, 2004).
- **RunTime Manager:** This component coordinates the interactions among the rest of components. First of all, it communicates with the Semantic Engine to verify that the information collected by the SearchBot is adequately mapped on the MGED ontology as a UIM and stored into YARS using RDF syntax. Secondly, it accepts the users' search requests through the GUI and hands them over the Query Factory, which, in turn queries YARS to retrieve all the metadata descriptions related to the particular search criteria. By retrieving a huge amount of metadata information from all the integrated data sources, the user benefits from a knowledge aware search response which is mapped to the underlying terminology and unified criteria of the UIM, with the added advantage that all resources can be tracked and identified separately.

FUTURE TRENDS

We believe that the SW and SW Services (SWS) paradigm promise a new level of data and process integration that can be leveraged to develop novel high-performance data and process management systems for biological applications.

Using semantic technologies as a key technology for interoperability of various datasets enables data integration of the vast amount of biological and biomedical data. In a nutshell, the use of knowledge-oriented biomedical data integration would lead to achieving Intelligent Biomedical Data Integration, which will bring biomedical research to its full potential.

A future trend of SAMIDI effort is to integrate it in a SWS scenario in order to achieve seamless integration, also from the service or process integration perspective. This would enable the access to a number of heterogeneous data resources which are accessed via a Web Service interface and it would open the scope and goals of SAMIDI to a broader base. Promising integrating efforts in that direction have already been undertaken by the Biomedical Information and Integration Discovery with SWS (BIRD) platform (Gómez, Rico, García-Sánchez, Liu & Terra, 2007), which

fosters the intelligent interaction between natural language user intentions and the existing SWS execution environments. BIRD is a platform designed to interact with humans as a gateway or a man-in-the-middle towards SWS execution environments. The main goal of the system is to help users express their needs in terms of information retrieval and achieve information integration by means of SWS. BIRD allows users to state their needs via natural language or using a list of terms extracted from the Gene Ontology, infer the goals derived from the users' wishes and send them to the suitable SWS execution environment, which will retrieve the outcome resulting of the integration of the applications being accessed (e.g. all the biomedical publications and medical databases).

CONCLUSION

SAMIDI, represents a tailor-made contribution aimed at tackling the problem of discovering, searching and integrating multiple micro-array data sources harnessing the distinctive features of semantic technologies. The main contribution of SAMIDI is that it makes a decomposition of the unmanageable problem of integrating different and independent micro-array data sources.

SAMIDI is the first step to foster and extend the idea of using semantic technologies for the integration of different data sources not only originated from micro-array research but stemming from biomedical research areas.

KEY TERMS

Bioinformatics: Application of information science and technologies for the management of biological data and the use of computers to store, compare, retrieve, analyze or predict the composition of the structure of biomolecules.

DNA Micro-Array: Collection of microscopic DNA spots attached to a solid surface forming an array for the purpose of expression profiling, which monitors expression levels for thousands of genes simultaneously.

MAGE: Standard micro-array data model and exchange format that is able to capture information specified by MIAME.

MGED: Ontology for micro-array experiments that establishes concepts, definitions, terms and resources for standardized description of a micro-array experiment in support of MAGE.

MIAME: XML based standard for the description of micro-array experiments, which stands for Minimum Information About a Micro-array Experiment.

Ontology: The specification of a conceptualization of a knowledge domain. It's a controlled vocabulary that describes objects and the relations among them in a formal way, and has a grammar for using the vocabulary terms to express something meaningful within a specified domain of interest.

Semantic Information Model Methodology: Set of activities, together with their inputs and outputs, aimed at the transformation of a collection of micro-

array data sources into a semantically integrated and unified representation of the information stored in the data sources.

Unifying Information Model (UIM): Construction that brings together all the physical data schemas related to the data sources to be integrated. It's built to represent an agreed-upon scientific view and vocabulary which will be the foundation to understand the data.

Mobile Robots Navigation, Mapping, and Localization Part I

Lee Gim Hee

DSO National Laboratories, Singapore

Marcelo H. Ang Jr.

National University of Singapore, Singapore

INTRODUCTION

The development of autonomous mobile robots is continuously gaining importance particularly in the military for surveillance as well as in industry for inspection and material handling tasks. Another emerging market with enormous potential is mobile robots for entertainment.

A fundamental requirement for autonomous mobile robots in most of its applications is the ability to navigate from a point of origin to a given goal. The mobile robot must be able to generate a collision-free path that connects the point of origin and the given goal. Some of the key algorithms for mobile robot navigation will be discussed in this article.

BACKGROUND

Many algorithms were developed over the years for the autonomous navigation of mobile robots. These algorithms are generally classified into three different categories: *global path planners*, *local navigation methods* and *hybrid methods*, depending on the type of environment that the mobile robot operates within and the robot's knowledge of the environment.

In this article, some of the key algorithms for navigation of a mobile robot are reviewed. Advantages and disadvantages of these algorithms shall be discussed. The algorithms that are reviewed include the *navigation function*, *roadmaps*, *vector field histogram*, *artificial potential field*, *hybrid navigation* and the *integrated algorithm*. Note that all the navigation algorithms that are discussed in this article assume that the robot is operating in a planar environment.

GLOBAL PATH PLANNERS

Global path planning algorithms refer to a group of navigation algorithms that plans an optimal path from a point of origin to a given goal in a known environment. This group of algorithms requires the environment to be free from dynamic and unforeseen obstacles. In this section, two key global path planning algorithms: *navigation functions* and *roadmaps* will be discussed.

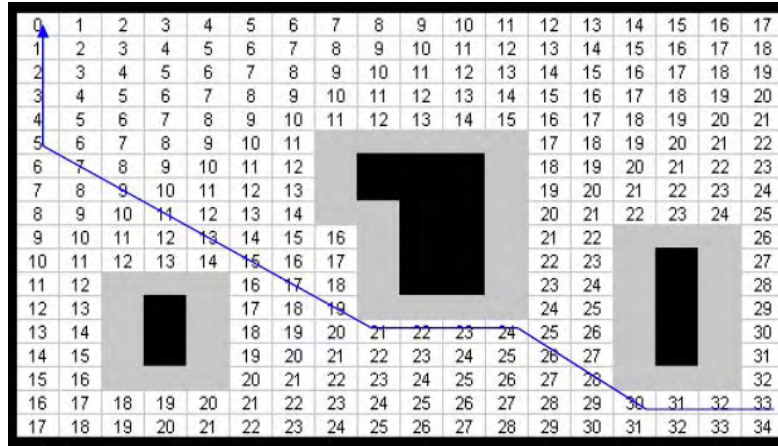

Navigation Functions

The most widely used global path planning algorithm is perhaps the navigation function computed from the "wave-front expansion" (J.-C Latombe, 1991; Howie Choset et al, 2005) algorithm due to its practicality, ease in implementation and robustness. The navigation function N is the *Manhattan distance* to the goal from the free space in the environment. The algorithm requires information of the environment provided to the robot to be represented as an array of grid cells.

Figure 1. The shaded cells are the 1-Neighbor of the cell (x, y) and the number shows the priority of the neighboring cells

| | | |
|---|--------|---|
| 2 | 3 | 4 |
| 1 | (x, y) | 5 |
| 8 | 7 | 6 |

Figure 2. Path generated by the navigation function

The navigation function assigns a numeric value N to each cell with the goal cell having the lowest value, and the other unoccupied cells having progressively higher values such that a steepest descent from any cell provides the path to the goal. The value of the unoccupied cell increases with the distance from the goal. Each grid cell is either free or occupied space denoted by gC_{free} and $gC_{occupied}$. First, the value of N is set to '0' at the goal cell gC_{goal} . Next, the value of N is set to '1' for every 1-Neighbor (see Figure 1 for the definition of 1-Neighbors) of gC_{goal} which is in gC_{free} . It is assumed that the distance between two 1-Neighbors is normalized to 1. In general, the value of each gC_{free} cell is set to $N+1$ (e.g., '2') for every unprocessed gC_{free} 1-Neighbor of the grid cell with value N (e.g., '1'). This is repeated until all the grid cells are processed.

Finally, a path to the goal is generated by following the steepest descent of the N values. To prevent the path from grazing the obstacles, the grid cells which are less than a safety distance α from the obstacles are omitted in the computation of the navigation function. Figure 2 shows a path generated by the navigation function. The black cells are the obstacles and the grey cells are the unsafe regions.

Roadmaps

A *roadmap* is a network of one-dimensional curves that captures the connectivity of free space in the en-

vironment (J.-C Latombe, 1991; Danner et al, 2000; Foskey et al, 2001; Isto P., 2002; T. Siméon et al, 2004; Xiaobing Zou et al, 2004; Howie Choset et al, 2005; Bhattacharya et al, 2007). Once a roadmap has been constructed, it is used as a set of standardized paths. Path planning is thus reduced to connecting the initial and goal positions to points in the roadmap. Various methods based on this general idea have been proposed. They include the *visibility graph* (Danner et al, 2000; Isto P., 2002; T. Siméon et al, 2004), *Voronoi diagram* (Foskey et al, 2001; Xiaobing Zou et al, 2004; Bhattacharya et al, 2007), *freeway net* and *silhouette* (J.-C Latombe, 1991; Howie Choset et al, 2005).

The *visibility graph* is the simplest form of *roadmap*. This algorithm assumes that the environment is made up of only polygonal obstacles. The nodes of a *visibility graph* include the point of origin, goal and all the vertices of the obstacles in the environment. The graph edges are straight line segments that connect any two nodes within the line-of-sight of each other. Finally, the shortest path from the start to goal can be obtained from the *visibility graph*.

Advantages and Disadvantages

The advantage of the *navigation functions*, *roadmaps* and other global path planning algorithms is that a continuous collision-free path can always be found by analyzing the connectivity of the free space. However,

these algorithms require the environment to be known and static. Any changes in the environment could invalidate the generated path. Hence, the navigation functions and other global path planning algorithms are usually not suitable for navigation in an initially unknown environment and those with dynamic and unforeseen obstacles.

LOCAL NAVIGATION METHODS

In contrast to the global path planners, local navigation methods do not require a known map of the environment to be provided to the robot. Instead, local navigation methods rely on current and local information from sensors to give a mobile robot online navigation capability. In this section, two of the key algorithms for local navigation: *artificial potential field* and *vector field histogram* will be evaluated.

Artificial Potential Field

The *artificial potential field* (O.Khatib, 1986) method, first introduced by Khatib, is perhaps the best known algorithm for local navigation of mobile robots due to its simplicity and effectiveness. The robot is represented as a particle in the configuration space q moving under the influence of an artificial potential produced by the goal configuration q_{goal} and the scalar distance to the obstacles. Typically the goal generates an attractive potential such as

$$U_g(q) = \frac{1}{2} K_g (q - q_g)^T (q - q_g) \quad (1)$$

which pulls the robot towards the goal, and each obstacle i produces repulsive potential such as

$$U_{i,o} = \begin{cases} \frac{1}{2} K_o \left(\frac{1}{d_i} - \frac{1}{d_o} \right)^2 & \text{if } d_i < d_o \\ 0 & \text{otherwise} \end{cases} \quad (2)$$

which pushes the robot away from the obstacle. In cases where there is more than one obstacle, the total repulsive force is computed by the sum of all the repulsive forces produced by the obstacles. K_g and K_o are the respective gains of the attractive and repulsive potential. d_i is the scalar distance between the robot and obstacle i . The repulsive potential will only have effect on the robot when its moves to a distance which is lesser than d_o . This implies that d_o is the minimum safe distance from the obstacle that the robot tries to maintain.

The negated gradient of the potential field gives the artificial force acting on the robot.

$$F(q) = -\nabla U(q) \quad (3)$$

Figure 3 shows the attractive force

$$F_g(q) = -K_g (q - q_g) \quad (4)$$

Figure 3. Robot's motion influenced by potential field

that is generated from the goal and the repulsive force

$$F_{i,o}(q) = \begin{cases} K_o \left(\frac{1}{d_i} - \frac{1}{d_o} \right) \frac{1}{d_i^2} & \text{if } d_i < d_o \\ 0 & \text{otherwise} \end{cases} \quad (5)$$

that is generated from an obstacle i . F_R is the resultant of all the repulsive forces and attractive force. Note that n denotes the total number of obstacles which is lesser than a distance d_o from the robot. At every position, the direction of this force is considered as the most promising direction of motion for the robot.

$$F_R(q) = F_g(q) + \sum_{i=1}^n F_{i,o}(q) \quad (6)$$

Vector Field Histogram

The *vector field histogram* method (Y.Koren et al, 1991; J.Borenstien, 1991; Zhang Huiliang et al, 2003) requires the environment to be represented as a tessellation of grid cells. Each grid cell holds a numerical value that ranges from 0 – 15. This value represents whether the environment represented by the grid cell is occupied or not. 0 indicates absolute certainty that the cell is not occupied and 15 indicates absolute certainty that the cell is occupied. A two stage data reduction process is carried out recursively to compute the desired motion of the robot at every instance of time.

In the first stage, the values of every grid cells that are in the vicinity of the robot's momentary location are reduced to a one-dimensional *polar histogram*. Each bin from the *polar histogram* corresponds to a direction as seen from the current location of the robot and it contains a value that represents the total sum of the grid cell values along that direction. The values from the *polar histogram* are also known as the *polar obstacle density* and they represent the presence of obstacles in the respective directions.

In the second stage, the robot selects the bin with a low *polar obstacle density* and direction closest to the goal. The robot moves in the direction represented by the chosen bin because this direction is free from obstacles and it will bring the robot closer to the goal.

Advantages and Disadvantages

The advantage of the *artificial potential field*, *vector field histogram* and other local navigation methods is that they do not include an initial processing step aimed at capturing the connectivity of the free space in a concise representation. Hence a prior knowledge of the environment is not needed. At any instant in time, the path is determined based on the immediate surrounding of the robot. This allows the robot to be able to avoid any dynamic obstacles in the robot's vicinity.

The major drawback of the local navigation methods is that they are basically steepest descent optimization methods. This renders the mobile robot to be susceptible to *local minima* (Y.Koren et al, 1991; J.-O. Kim et al, 1992; Liu Chengqing et al, 2000; Liu Chengqing, 2002; Min Gyu Park et al, 2004). A *local minimum* in the *potential field* method occurs when the attractive and the repulsive forces cancel out each other. The robot will be immobilized when it falls into a *local minimum*, and loses the capability to reach its goal. Many methods have been proposed to solve the *local minima* problem (J.-O. Kim et al, 1992; Liu Chengqing et al, 2000; Liu Chengqing, 2002; Min Gyu Park et al, 2004). For example, Liu Chengqing (Liu Chengqing et al, 2000; Liu Chengqing, 2002) has proposed the virtual obstacle method where the robot detects the *local minima* and fills the area with artificial obstacles. Consequently, the method closes all concave obstacles and thus avoiding *local minima* failures. Another method was proposed by Jin-Oh Kim (J.-O. Kim et al, 1992) to solve the *local minima* problem. This method uses *local minima free* harmonic functions based on fluid dynamics to build the artificial potentials for obstacle avoidances.

HYBRID METHODS

Another group of algorithms suggest a combination of the local navigation and global path planning methods. These algorithms aim to combine the advantages from both the local and global methods, and to also eliminate some of their weaknesses. In this section, two key hybrid methods algorithms: *hybrid navigation* and *integrated algorithm* will be reviewed.

Figure 4. Illustration of the hybrid navigation algorithm

Hybrid Navigation

Figure 4 shows an illustration of the *hybrid navigation algorithm* (Lim Chee Wang, 2002; Lim Chee Wang et al, 2002). This algorithm combines the *navigation function* with the *potential field* method. It aims to eliminate local minima failures and at the same time does online collision avoidance with dynamic obstacles.

The robot first computes the path joining its current position to the goal using the *navigation function*. The robot then places a circle with an empirical radius centered at its current position. The cell that corresponds to the intersection of the circle with the *navigation function* path is known as the attraction point. The attraction point is the cell with the lowest N value if there is more than one intersection.

The robot advances towards the attraction point using the *potential field* method and the circle moves along with the robot which will cause the attraction point to change. As a result, the robot is always chasing after a dynamic attraction point which will progress towards the goal along the *local minima free navigation function* path. The radius of the circle is made larger to intersect the *navigation function* path in cases where no intersections are found. The radius of the circle is reduced to smaller than the distance between the robot and its

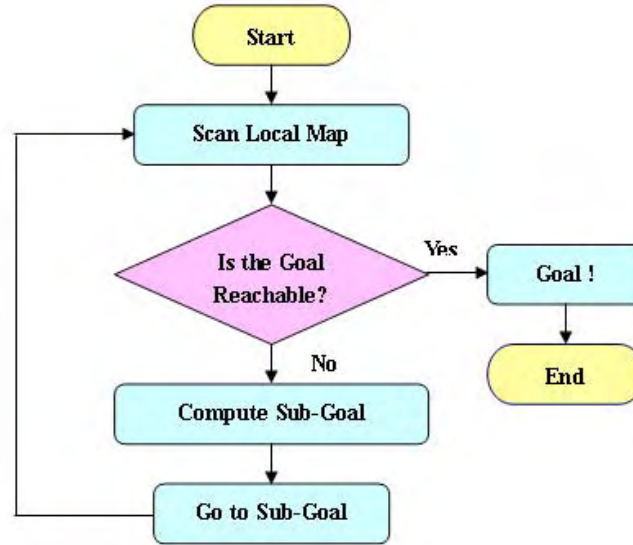

goal when the distance between the robot and its goal becomes smaller than the radius of the circle. This is to make sure that the N value of the next intersection will be smaller than the current N value.

Integrated Algorithm

In recent years, the *integrated algorithm* (Lee Gim Hee, 2005; Lee Gim Hee et al, 2007) has been proposed to give a mobile robot the ability to plan *local minima* free paths and does online collision avoidance to dynamic obstacles in an unknown environment. The algorithm modifies the *frontier-based exploration* method (Brian Yamauchi, 1997), which was originally used for map building, into a path planning algorithm in an unknown environment. The modified *frontier-based exploration* method is then combined with the *hybrid navigation* algorithm into a single framework.

Figure 5 shows an overview of the *integrated algorithm*. The robot first builds a local map (see Part II of this article for details on map building) of its surrounding. It then decides whether the goal is reachable based on the acquired local map. The goal is reachable if it is in free space, and is not reachable if it is in the unknown space. Note that an unknown region is a part of the map which has not been explored during the map building

Figure 5. The integrated algorithm

process. The robot will advance towards the goal using the *hybrid navigation* algorithm if it is reachable or advance towards the sub-goal and build another local map at the sub-goal if the goal is not reachable. This map will be added to the previous local maps to form a larger map of the environment. The process goes on until the robot finds the goal within a free space.

The sub-goal is computed in three steps. First, compute the path that joins the robot's current position and the goal using the *navigation function*. The unknown cells are taken to be free space in the computation of the *navigation function*. Second, all the frontiers in the map are computed. The boundary of free space and unknown region is known as the frontier. A frontier is made up of a group of adjacent frontier cells. The frontier cell is defined as any gC_{free} cell on the map with at least two unknown cells $gC_{unknown}$ as its immediate neighbor. The total number of frontier cells that make up a frontier must be larger than the size of the robot to make that frontier valid. Third, the frontier that intersects the navigation function path will be selected and its centroid chosen as the sub-goal.

Advantages and Disadvantages

The *hybrid navigation* algorithm has the advantage of eliminating local minima failures and at the same time doing online collision avoidance with dynamic obstacles. However, it requires the environment to be fully known for the search of a navigation function path to the goal. The algorithm will fail in a fully unknown environment. It also does not possess any capability to re-plan the *navigation function* path during an operation. Therefore any major changes to the environment could cause failure in the algorithm.

The integrated algorithm has the advantages of planning local minima free paths, does online collision avoidance to dynamic obstacles in totally unknown environments. In addition, the algorithm gives the mobile robot a higher level of autonomy since it does not depend on humans to provide a map of the environment. However, the advantages come with the trade off of tedious implementations. This is because the integrated algorithm requires both the *hybrid navigation* algorithm and a good mapping algorithm to be implemented at the same time.

CONCLUSION

Mobile robot navigation involves more than planning a path from a point of origin to a given goal. A mobile robot must be able to follow the planned path closely and avoid any dynamic or unforeseen obstacles during its journey to the goal. Some of the key algorithms that give a mobile robot navigation capability were discussed in this article. These algorithms include the *navigation function*, *roadmaps*, *artificial potential field*, *vector field histogram*, *hybrid navigation* and the *integrated algorithm*.

FUTURE TRENDS

The assumption that on-board sensors have perfect sensing capability is generally made by researchers researching on mobile robot navigation. In reality, these sensors are corrupted with noise and this usually causes adverse effects on the performance of the navigation algorithms. The greatest challenge for a robust implementation of the navigation algorithms is therefore to minimize the adverse effects caused by the sensor uncertainty.

KEY TERMS

Global Path Planner: A group of navigation algorithms for planning an optimal path that connects a point of origin to a given goal in a known environment.

Graph Edge: Graph edge is usually drawn as a straight line in a graph to connect the nodes. It is used to represent connectivity between two or more nodes and may carry additional information such as the Euclidean distance between the nodes.

Graph Node: Graph Node is also known as graph vertex. It is a point on which the graph is defined and maybe connected by graph edges.

Hybrid Methods: A group of navigation methods that combine the global path planning and local navigation algorithms. The objective is to combine the advantages eliminate the inherent weaknesses of both groups of algorithms.

Local Minima: It is also known as relative minima. Local minimum refers to a minimum within some neighborhood and it may not be a global minimum.

Local Navigation Methods: A group of navigation algorithms that do not require a known map of the environment to be provided to the robot. Instead, local navigation methods rely on current and local information from sensors to give a mobile robot online navigation capability.

Manhattan Distance: The distance between two points measured along axes at right angles. For example, given two points p_1 and p_2 in a two-dimensional plane at (x_1, y_1) and (x_2, y_2) respectively, the Manhattan distance between p_1 and p_2 is given by $|x_1 - x_2| + |y_1 - y_2|$.

Mobile Robots Navigation, Mapping, and Localization Part II

INTRODUCTION

In addition to the capability to navigate from a point of origin to a given goal and avoiding all static and dynamic obstacles, a mobile robot must possess another two competencies: *map building* and *localization* in order to be useful.

A mobile robot acquires information of its environment via the process of map building. Map building for mobile robots are commonly divided into *occupancy grid* and *topological* maps. *Occupancy-grid* maps seek to represent the geometric properties of the environment. *Occupancy-grid* mapping was first suggested by Elfes in 1987 and the idea was published in his Ph.D. thesis (A. Elfes, 1989) in 1989. *Topological* mapping was first introduced in 1985 as an alternative to the *occupancy-grid* mapping by R. Chatila and J.-P. Laumond (R. Chatila, & J.-P. Laumond, 1985). *Topological* maps describe the connectivity of different locations in the environment.

The pose of a mobile robot must be known at all times for it to navigation and build a map accurately. This is the problem of localization and it was first described in the late 1980's by R. Smith et al (R. Smith et al, 1980). Some key algorithms for map building and localization will be discussed in this article.

BACKGROUND

Map building is the process of acquiring information of the environment via sensory data and representing the acquired information in a format that is comprehensible to the robot. The acquired map of the environment can be used by the robot to improve its performance in navigation.

Localization is the process of finding the pose of the robot in the environment. It is perhaps the most

important competency that a mobile robot must possess. This is because the robot must know its pose in the environment before it can plan its path to the goal or follow a planned path towards the goal.

In this article, two key algorithms for map building: *occupancy-grid* and *topological* mapping are discussed. The *occupancy grid* and *topological* maps are two different methodologies to represent the environment in a robot's memory. Two key localization methods: Localization with *Kalman filter* and *particle filter* are also reviewed.

MAP BUILDING

As seen from the *integrated algorithm* from part I of the article, a mobile robot must be able to acquire maps of an unknown environment to achieve higher level of autonomy. Map building is the process where sensory information of the surrounding is made comprehensive to a mobile robot. In this section, two key approaches for map building: *occupancy-grid* and *topological* mapping are discussed.

Occupancy-Grid Maps

Occupancy-grid maps (H.P. Moravec, 1988; H.P. Moravec et al, 1989; A. Elfes, 1987, A. Elfes, 1989; S. Thrun et al, 2005) represent the environment as a tessellation of grid cells. Each of the grid cells corresponds to an area in the physical environment and holds an occupancy value which indicates the probability of whether the cell is occupied or free. The occupancy value of the i^{th} grid cell at current time t will be denoted by $p_{t,i}$. Note that $p_{t,i}$ must be within the range of 0 to 1 following the axioms of probability. $p_{t,i} = [0,0.5)$ indicates the confidence level of a cell being empty where 0 indicates absolute certainty that the cell is empty. $p_{t,i}$

$= (0.5, 1]$ indicates the confidence level of a cell being occupied where 1 indicates absolute certainty that the cell is occupied. $p_{t,i} = 0.5$ indicates that the cell is an unexplored area.

A robot does not have any knowledge of the world when it was first placed in an unknown environment. It is therefore intuitive to set $p_{t,i} = 0.5$ for all i at time $t = 0$. The map is updated via the *log odds* (S. Thrun et al, 2005) representation of occupancy. The advantage of *log odds* representation is that it can avoid numerical instabilities for probability near 0 or 1. The i^{th} grid cell that intercepts the sensor line of sight is updated according to

$$l_{t,i} = l_{t-1,i} + l_{\text{sensor}} \quad (1)$$

where $l_{t-1,i}$ is the *log odds* computed from the occupancy value of the cell at $t-1$.

$$l_{t-1,i} = \log \frac{p_{t-1,i}}{1 - p_{t-1,i}} \quad (2)$$

$l_{\text{sensor}} = l_{\text{occ}}$ if the cell corresponds to the sensor measurement and $l_{\text{sensor}} = l_{\text{free}}$ if the range to the cell is shorter

than the sensor measurement. The other cells in the map remain unchanged.

Figure 1(a) illustrates the update process for the map. The cell that corresponds to the sensor measurement is shaded black and all the cells that intercept the sensor measurement beam are shaded white. Figure 1(b) shows a case where the sensor measurement equals to maximum sensor range and $l_{\text{sensor}} = l_{\text{free}}$ for all cells that intercepts the sensor beam. This is because it is assumed that no obstacle is detected if the sensor measurement equals to maximum sensor range. l_{occ} and l_{free} are computed from

$$l_{\text{occ}} = \log \frac{p_{\text{occ}}}{1 - p_{\text{occ}}} \text{ and } l_{\text{free}} = \log \frac{p_{\text{free}}}{1 - p_{\text{free}}} \quad (3)$$

where p_{occ} and p_{free} denote the probabilities of the sensor measurement correctly deducing whether a grid cell is occupied or empty. The two probabilities must add up to 1 and their values depend on the accuracy of the sensor. p_{occ} and p_{free} will have values closer to 1 and 0 for an accurate sensor. The values of p_{occ} and p_{free} have to be determined experimentally and remain constant in the map building process.

Figure 1. Updating an occupancy grid map (a) when an obstacle is detected (b) when a maximum range measurement is detected, i.e. it is assumed that in this case no obstacle is detected

Figure 2. Occupancy grid map of the corridor along block EA level 3 in the Faculty of Engineering of the National University of Singapore (NUS)

The occupancy value of a grid cell is easily recovered from

$$p_{t,i} = 1 - \frac{1}{1 + \exp\{l_{t,i}\}} \quad (4)$$

Figure 2 shows an occupancy grid map of the corridor along block EA level 3 in the Faculty of Engineering of the National University of Singapore (NUS) acquired with a laser range finder. The black regions denote obstacles, white regions denote free space and grey regions denote unexplored areas.

Topological Maps

Unlike the *occupancy grid* maps, topological maps (D. Kortenkamp et al, 1994; H. Choset, 1996; H. Choset et al, 1996) do not attempt to represent the geometric information of the environment. Instead, *topological* maps represent the environments as *graphs*. An example of the topological map is shown in Figure 3. List of significant features such as walls, corners, doors or corridors are represented as nodes m_i and connectivity

Figure 3. Example of a topological map. The features are represented as nodes m_i . The connectivity and distance between features are represented as edges u_{jk}

between adjacent features is represented as edges u_{jk} . In many *topological* maps, distances between adjacent features are also represented by the edges connecting the nodes. The success of the *topological* maps depends greatly on the efficiency in features extraction. Examples of feature extraction algorithms can be found in (Martin David Adams, 1999; Sen Zhang et al, 2003; Jodo Xavier et al, 2005).

Topological maps are better choice for mapping if memory space is a major concern. This is because less memory is required to store the nodes as compared to the large number of grid cells in occupancy grid maps. The advantage of less memory consumption for the *topological* map however comes with the tradeoff of being less accurate. This is because some important information such as precise location of the free spaces in the environment may not be represented in the maps. The limited accuracy of *topological* maps thus restricts the robot's capability for fast and safe navigation.

LOCALIZATION

Most mobile robots localize their pose x_t with respect to a given map based on odometry readings. Unfortunately, wheel slippages and drifts cause incremental localization errors (J. Borenstein et al, 1995; J. Borenstein et al, 1996). These errors cause the mobile robot to lose track of its own pose and hence losing the ability to navigate autonomously from one given point in the map to another. The solution to the localization problem is to make use of information of the environment from additional sensors. Examples of sensors used are laser range finder and sonar sensor that measure the distance between the robot and the nearest obstacles in the environment. The *extended Kalman filter* (EKF) and *particle filter* are two localization algorithms that use odometry and additional sensory data of the environment to localize a mobile robot. Both algorithms are probabilistic methods that allow uncertainties from the robot pose estimate and sensor readings to be accounted for in a principled way.

Localization with Extended Kalman Filter

EKF (John J. Leonard et al, 1991; A.Kelly, 1994; G. Welch et al, 1995; Martin David Adams, 1999; S. Thrun et al, 2005) is perhaps the most established algorithm for localization of mobile robots because of its robust-

ness and efficiency. The EKF is a recursive algorithm for estimating the pose of the robot with noisy sensor readings. A key feature of the EKF is that it maintains a posterior belief $bel(x_t)$ of the pose estimate, which follows a *Gaussian distribution*, represented by a mean x_t and covariance P_t . The mean x_t represents the most likely pose of the robot at time t and covariance P_t represents the error covariance of this estimate. The EKF consists of two steps: the prediction and update steps. In the prediction step, the predicted belief $\overline{bel}(x_t)$ is first computed using a motion model which describes the state dynamics of the robot. $\overline{bel}(x_t)$ is subsequently transformed into $bel(x_t)$ by incorporating the sensor measurements in the update step.

As mentioned above, the predicted belief $\overline{bel}(x_t)$ which is represented by the predicted mean \bar{x}_t and covariance \bar{P}_t is computed from the prediction step given by

$$\bar{x}_t = f(x_{t-1}, u_t) \quad (5)$$

$$\bar{P}_t = F_t P_{t-1} F_t^T + Q_t \quad (6)$$

where $f(\cdot)$ is the motion model of the mobile robot, F is the Jacobian of $f(\cdot)$ evaluated at x_{t-1} , Q_t is the covariance of the motion model and u_t is the control data of the robot.

$\overline{bel}(x_t)$ is subsequently transformed into $bel(x_t)$ by incorporating the sensor measurement z_t into the update step of the EKF shown in Equations 7, 8 and 9.

$$K_t = \bar{P}_t H_t^T (H_t \bar{P}_t H_t^T + R_t)^{-1} \quad (7)$$

$$x_t = \bar{x}_t + K_t (z_t - h(\bar{x}_t, m)) \quad (8)$$

$$P_t = (I - K_t H_t) \bar{P}_t \quad (9)$$

K_t , computed in Equation 7, is called the *Kalman gain*. It specifies the degree to which z_t should be incorporated into the new pose estimate. Equation 8 computes x_t by adjusting it in proportion to K_t and the deviation of the z_t with the predicted measurement $h(\bar{x}_t, m)$. It is important to note that the sensor measurement $z_t = [z_t^1 \ z_t^2 \ \dots]^T$ refers to coordinates of a set of observed landmarks instead of the raw sensor readings and the sensor measurement model $h(\cdot)$ gives the predicted measurement from the given topological map m and \bar{x}_t . H_t is the Jacobian of $h(\cdot)$ evaluated at x_{t-1} . Finally, the covariance

P_t of the posterior belief $bel(x_t)$ is computed in Equation 9 by adjusting for the information gain resulting from the sensor measurements.

Localization with Particle Filter

In the recent years, there is an increasing interest in the use of particle filter (S. Thrun et al, 2001; C. Kwok et al, 2002; D. Fox et al, 2003; Ioannis M. Rekleitis, 2004; S. Thrun et al, 2005) over EKF for robot localization. This increased interest is likely due to four reasons. First, raw sensor measurements of the environment are used in particle filter localization where the EKF localization requires feature extraction. Second, the particle filter is more robust because unlike the EKF, it does not assume Gaussian distribution for the posterior belief $bel(x_t)$. Third, the particle filter is able to recover from localization failure. Localization failure occurs if the robot suddenly loses track of its pose during the localization process. Localization failure is also known as the kidnapped problem. Fourth, unlike the EKF there is no need to derive complicated Jacobians for the particle filter.

The intuition behind the particle filter is to represent the posterior belief $bel(x_t)$ by a finite sample set of M weighted particles. This sample set is drawn according to $bel(x_t)$. The particles set is denoted by

$$\xi_t = \chi_t^{[1]}, \chi_t^{[2]}, \dots, \chi_t^{[M]} \quad (10)$$

where

$$\chi_t^{[m]} = [x_t^{[m]} \quad w_t^{[m]}]^T$$

denotes the m^{th} particle. Here, $x_t^{[m]}$ is a random variable that represents a hypothesized state and $w_t^{[m]}$ is a non-negative value called the importance factor which represents the weight of each particle. Similar to the EKF, the particle filter consists of the prediction and update steps. In the prediction step, samples of the particles are drawn from a motion model of the robot to represent the predicted belief $\overline{bel}(x_t)$. The particles are then weighted according to the sensor measurements in the update step. Finally, $\overline{bel}(x_t)$ is transformed into the posterior belief $bel(x_t)$ by resampling the particles according to their weights.

Table 1 shows an iteration of the recursive particle filter algorithm for localization. The inputs to the particle filter are the set of particles representing the previous state belief ξ_{t-1} , the most recent control actions u_t and measurement data z_t . Line 3 is the prediction step that generates the hypothetical state $x_t^{[m]}$ by sampling from the motion model $p(x_t | u_t, x_{t-1}^{[m]})$ of the robot. The set of particles obtained after M iterations represents $\overline{bel}(x_t)$. Line 4 computes $w_t^{[m]}$ from the sensor measurement

model. The importance factor accounts for the mismatch between $\overline{bel}(x_i)$ and $bel(x_i)$. Finally, the resampling process from line 7 to 9 draws with replacement M particles from the temporary set ξ_i with a probability proportional to the importance factors. The distribution of $\overline{bel}(x_i)$ is transformed into $bel(x_i)$ by incorporating the importance factors in the resampling process.

Figure 4(a) to (d) shows an implementation result of a robot localizing itself in a corridor. The particle set is initialized to the initial known pose of the robot show in Figure 4(a). The particles are initialized uniformly within a circle with radii 100mm and the initial position of the robot is taken as the center. The orientation of the particles is also initialized uniformly within $\pm 5^\circ$ to

M

Figure 4. Implementation of the particle filter to solve the localization problem. Notice that the error from the odometry grows as the robot travels a greater distance

the initial orientation of the robot. This is to eliminate possible errors in estimating the initial pose of the robot. Figure 4(b) to 4(d) show that the error from the odometry grows as the robot travels a greater distance. The robot thinks that it is traveling in occupied space if it relied solely on the odometry readings and this is obviously wrong. It is apparent that the particle filter gives a more reasonable pose estimate because the robot is always moving within the free space.

It was mentioned earlier that the particle filter is able to recover from localization failure. An example of localization failure is when the robot is pushed by human resulting in a mismatch between the true and estimated pose of the robot. Fortunately, the problem can be easily solved by observing the total weights of the filter after each iteration. Localization failures will cause sharp drops in the total weights of the particles. The particles are re-initialized uniformly in the free space after detecting a sharp drop in the total weights of the particles. The particles will eventually converge to the true pose of the robot.

The particle filter is a powerful algorithm in solving the localization problem. However, it must be noted that the number of particles used to represent beliefs is an important parameter for efficiency of the particle filter in recovering from localization failures. A large size of particles is necessary to recover from localization failures in large environments and in many cases the maximum number particles is restricted by the available computing resources. This problem is also known as the *curse of dimensionality*.

CONCLUSION

A mobile robot has to possess three competencies to achieve full autonomy: navigation, map building and localization. Over the years, many algorithms have been proposed and implemented with notable success to give mobile robots all the three competencies. Some of the key algorithms such as the *navigation function*, *roadmaps*, *artificial potential field*, *vector field histogram*, *hybrid navigation* and the *integrated algorithm* for navigation; *occupancy grid* and *topological* based mapping; as well as the *Kalman filter* and *particle filter* for localization are reviewed in both Part I and II of this article.

FUTURE TRENDS

While the navigation, map building and localization algorithms are implemented with notable success, the scale and structure of the environments for these algorithms to work are limited. Hence, the future challenges for mobile robot autonomy are in the implementations of the algorithms in larger scale and more complex environments such as the urban cities or jungles.

KEY TERMS

Curse of Dimensionality: This term was first used by Richard Bellman. It refers to the problem of exponential increase in volume associated with adding extra dimensions to a mathematical space.

Gaussian Distribution: It is also known as normal distribution. It is a family of continuous probability distributions where each member of the family is described by two parameters: mean and variance. This form of distribution is used by the localization with *extended Kalman filter* algorithm to describe the posterior belief distribution of the robot pose.

Jacobians: The Jacobian is a first-order partial derivatives of a function. Its importance lies in the fact that it represents the best linear approximation to a differentiable function near a given point.

Odometry: A method to do position estimation for a wheeled vehicle during navigation by counting the number of revolutions taken by the wheels that are in contact with the ground.

Posterior Belief: It refers to the probability distribution of the robot pose estimate conditioned upon information such as control and sensor measurement data. The *extended Kalman filter* and *particle filter* are two different methods for computing the posterior belief.

Predicted Belief: It is also known as the prior belief. It refers to the probability distribution of the robot pose estimate interpreted from the known control data and in the absence of the sensor measurement data.

Recursive Algorithm: It refers to a type of computer function that is applied within its own definition. The

extended Kalman filter and *particle filter* are recursive algorithms because the outputs from the filters at the

current time step are used as inputs in the next time step.

Modal Logics for Reasoning about Multiagent Systems

M

Nikolay V. Shilov

Russian Academy of Science, Institute of Informatics Systems, Russia

Natalia Garanina

Russian Academy of Science, Institute of Informatics Systems, Russia

INTRODUCTION

It becomes evident in recent years a surge of interest to applications of modal logics for specification and validation of complex systems. It holds in particular for combined logics of knowledge, time and actions for reasoning about multiagent systems (Dixon, Nalon & Fisher, 2004; Fagin, Halpern, Moses & Vardi, 1995; Halpern & Vardi, 1986; Halpern, van der Meyden & Vardi, 2004; van der Hoek & Wooldridge, 2002; Lomuscio, & Penczek, W., 2003; van der Meyden & Shilov, 1999; Shilov, Garanina & Choe, 2006; Wooldridge, 2002). In the next paragraph we explain what are logics of knowledge, time and actions from a viewpoint of mathematicians and philosophers. It provides us a historic perspective and a scientific context for these logics.

For mathematicians and philosophers logics of actions, time, and knowledge can be introduced in few sentences. A logic of actions (ex., Elementary Propositional Dynamic Logic (Harel, Kozen & Tiuryn, 2000)) is a polymodal variant of a basic modal logic **K** (Bull & Segerberg, 2001) to be interpreted over arbitrary Kripke models. A logic of time (ex., Linear Temporal Logic (Emerson, 1990)) is a modal logic with a number of modalities that correspond to “next time”, “always”, “sometimes”, and “until” to be interpreted in Kripke models over partial orders (discrete linear orders for LTL in particular). Finally, a logic of knowledge or epistemic logic (ex., Propositional Logic of Knowledge (Fagin, Halpern, Moses & Vardi, 1995; Rescher, 2005)) is a polymodal variant of another basic modal logic **S5** (Bull & Segerberg, 2001) to be interpreted over Kripke models where all binary relations are equivalences.

BACKGROUND: MODAL LOGICS

All **modal logics** are languages that are characterized by syntax and semantics. Let us define below a very simple modal logic in this way. This logic is called **Elementary Propositional Dynamic Logic (EPDL)**.

Let *true*, *false* be Boolean constants, *Prp* and *Rel* be disjoint sets of propositional and relational variable respectively. The syntax of the classical propositional logic consists of formulas which are constructed from propositional variables and Boolean connectives “¬” (negation), “&” (conjunction), “∨” (disjunction), “→” (implication), and “↔” (equivalence) in accordance with the standard rules. EPDL has additional formula constructors, modalities, which are associated with relational variables: if *r* is a relational variable and φ is a formula of EPDL then

- $([r]\varphi)$ is a formula which is read as “box *r*- φ ” or “after *r* always φ ”;
- $(\langle r \rangle \varphi)$ is a formula which is read as “diamond *r*- φ ” or “after *r* sometimes φ ”.

The semantics of EPDL is defined in models, which are called **labeled transition systems** by computer scientists and **Kripke models**¹ by mathematicians and philosophers. A model *M* is a pair (D, I) where the domain (or the universe) $D \neq \emptyset$ is a set, while the interpretation *I* is a pair of mappings (P, R) . Elements of the domain *D* are called states by computer scientists and worlds by mathematicians and philosophers. The interpretation maps propositional variables to sets of states $P: Prp \rightarrow 2^D$ and relational variables to binary relations on states $R: Rel \rightarrow 2^{D \times D}$. We write $I(p)$ and

$I(r)$ instead of $P(p)$ and $R(r)$ whenever it is implicit that p and r are propositional and relational variables respectively.

Every model $M = (D, I)$ can be viewed as a directed graph with nodes and edges labeled by propositional and action variables respectively. Its nodes are states of D . A node $s \in D$ is marked by a propositional variable $p \in Prp$ iff $s \in I(p)$. A pair of nodes $(s_1, s_2) \in D \times D$ is an edge of the graph iff $(s_1, s_2) \in I(r)$ for some relational variable $r \in Rel$; in this case the edge (s_1, s_2) is marked by this relational variable r . Conversely, a graph with nodes and edges labeled by propositional and relational variables respectively can be considered as a model.

For every model $M = (D, I)$ the **entailment** (validity, satisfiability) **relation** \models_M between states and formulas can be defined by induction on formula structure:

- for every state $s \models_M true$ and not $s \models_M false$;
- for any state s and propositional variable p , $s \models_M p$ iff $s \in I(p)$;
- for any state s and formula ϕ , $s \models_M (\neg\phi)$ iff it is not the case $s \models_M \phi$;
- for any state s and formulas ϕ and ψ ,
 $s \models_M (\phi \& \psi)$ iff $s \models_M \phi$ and $s \models_M \psi$;
 $s \models_M (\phi \vee \psi)$ iff $s \models_M \phi$ or $s \models_M \psi$;
- for any state s , relational variable r , and formula ϕ ,
 $s \models_M ([r]\phi)$ iff $(s, s') \in I(r)$ and $s' \models_M \phi$ for every state s' ;
 $s \models_M (\langle r \rangle \phi)$ iff $(s, s') \in I(r)$ and $s' \models_M \phi$ for some state s' .

Semantics of the above kind is called **possible worlds semantics**.

Let us explain EPDL pragmatics by the following puzzle example.

Alice and Bob play the Number Game. Positions in the game are integers in $[1..109]$. An initial position is a random number. Alice and Bob make alternating moves: Alice, Bob, Alice, Bob, etc. Available moves are same for both: if a current position is $n \in [1..99]$ then $(n+1)$ and $(n+10)$ are possible next positions. A player wins the game iff the opponent is the first to enter $[100..109]$. Problem: Find all initial positions where Alice has a winning strategy.

Kripke model for the game is quite obvious:

- States correspond to game positions, i.e. integers in $[1..109]$.
- Propositional variable *fail* is interpreted by $[100..109]$.
- Relational variable *move* is interpreted by possible moves.

Formula $\neg fail \& \langle move \rangle (\neg fail \& [move] fail)$ is valid in those states where the game is not lost, there exists a move after which the game is not lost, and then all possible moves always lead to a loss in the game. Hence this EPDL formula is valid in those states where Alice has a 1-round winning strategy against Bob.

COMBINING KNOWLEDGE, ACTIONS AND TIME

Logic of Knowledge

Logics of knowledge are also known as **epistemic logics**. One of the simplest epistemic logic is **Propositional Logic of Knowledge for $n > 0$ agents (PLK_n)** (Fagin, Halpern, Moses & Vardi, 1995). A special terminology, notation and **Kripke models** are used in this framework. A set of relational symbols *Rel* in PLK_n consists of natural numbers $[1..n]$ representing names of agents. Notation for modalities is: if $i \in [1..n]$ and ϕ is a formula, then $(Ki \phi)$ and $(Si \phi)$ are used instead of $([i] \phi)$ and $(\langle i \rangle \phi)$. These formulas are read as “(an agent) i knows ϕ ” and “(an agent) i can suppose ϕ ”. For every agent $i \in [1..n]$ in every model $M = (D, I)$, interpretation $I(i)$ is an “**indistinguishability relation**”, i.e. an equivalence relation² between states that the agent i can not distinguish. Every model M , where all agents are interpreted in this way, is denoted as $(D, \sim_1, \dots, \sim_n, I)$ with explicit $I(I) = \sim_1, \dots, I(n) = \sim_n$ instead of brief standard notation (D, I) . An agent knows some “fact” ϕ in a state s of a model M , if the fact is valid in every state s' of this model that the agent can not distinguish from s :

- $s \models_M (K_i \phi)$ iff $s' \models_M \phi$ for every state $s' \sim_i s$.

Similarly, an agent can suppose a “fact” ϕ in a state s of a model M , if the fact is valid in some state s' of this model that the agent can not distinguish from s :

- $s \models_M (S_i \varphi)$ iff $s' \models_M \varphi$ for some state $s' \sim_i s$.

The above possible worlds semantics of knowledge is due to pioneering research (Hintikka, 1962).

Temporal Logic with Actions

Another propositional polymodal logic is **Computational Tree Logic with actions (Act-CTL)**. *Act-CTL* is a variant of a basic propositional branching time temporal logic Computational Tree Logic (CTL) (Emerson, 1990; Clarke, Grumberg & Peled, 1999). In *Act-CTL* the set of relational symbols consists of action symbols *Act*. Each action symbol can be interpreted by an “instant action” that is executable in one undividable moment of time.

Act-CTL notation for basic modalities is: if $b \in Act$ and φ is a formula, then $(A_b X \varphi)$ and $(E_b X \varphi)$ are used instead of $([b] \varphi)$ and $(\langle b \rangle \varphi)$. But syntax of *Act-CTL* has also some other special constructs associated with action symbols: if $b \in Act$ and φ and ψ are formulas, then $(A_b G \varphi)$, $(A_b F \varphi)$, $(E_b G \varphi)$, $(E_b F \varphi)$, $A_b(\varphi U \psi)$ and $E_b(\varphi U \psi)$ are also formulas of *Act-CTL*. In formulas of *Act-CTL* prefix “A” is read as “for every future”, “E” – “for some future”, suffix “X” – “next state”, “G” – “always” or “globally”, “F” – “sometimes” or “future”, the infix “U” – “until”, and a sub-index “b” is read as “in b-run(s)”.

We have already explained semantics of $(A_b X \varphi)$ and $(E_b X \varphi)$ by referencing to $([b] \varphi)$ and $(\langle b \rangle \varphi)$. Constructs “ $A_b G$ ”, “ $A_b F$ ”, “ $E_b G$ ”, and “ $E_b F$ ” can be expressed in terms of “ $A_b(\dots U \dots)$ ” and “ $E_b(\dots U \dots)$ ”, for example: $(E_b F \varphi) \leftrightarrow E_b(true U \varphi)$. Thus let us define below semantics of “ $A_b(\dots U \dots)$ ” and “ $E_b(\dots U \dots)$ ” only. Let $M = (D, I)$ be a model. If $b \in Act$ is an action symbol, then a partial *b*-run is a sequence of states $s_0 \dots s_k s_{(k+1)} \dots \in D$ (maybe infinite) such that $(s_k, s_{(k+1)}) \in I(b)$ for every consecutive pair of states within this sequence. If $b \in Act$ is an action symbol, then a *b*-run is an infinite partial *b*-run or finite *b*-run that can not be continued³. Then semantics of constructs “ $A_b(\dots U \dots)$ ” and “ $E_b(\dots U \dots)$ ” can be defined as follows:

- $s \models_M A_b(\varphi U \psi)$ iff for every *b*-run $s_0 \dots s_k \dots$ that starts in s (i.e. $s_0 = s$) there exists some $n \geq 0$ for which $s_n \models_M \psi$ and $s_k \models_M \varphi$ for every $k \in [0..(n-1)]$;
- $s \models_M E_b(\varphi U \psi)$ iff for some *b*-run $s_0 \dots s_k \dots$ that starts in s (i.e. $s_0 = s$) there exists some $n \geq 0$ for which $s_n \models_M \psi$ and $s_k \models_M \varphi$ for every $k \in [0..(n-1)]$.

The standard branching-time temporal logic *CTL* can be treated as **Act-CTL** with a single implicit action symbol.

Combined Logic of Knowledge, Actions and Time

There are many **combined polymodal logics** for reasoning about multiagent systems. Maybe the most advanced is **Belief-Desire-Intention (BDI) logic** (Wooldridge, 1996; Wooldridge, 2002). An agent’s beliefs correspond to information the agent has about the world. (This information may be incomplete or incorrect. An agent’s knowledge in BDI is just a true belief.) An agent’s desires correspond to the allocated tasks. An agent’s intentions represent desires that it has committed to achieving. Admissible actions are actions of individual agents; they may be constructed from primitive actions by means of composition, non-deterministic choice, iteration, and parallel execution. But semantics of BDI and reasoning in BDI are quite complicated for a short encyclopedia article.

In contrast, let us discuss below a simple example of a combined logic of knowledge, actions and time – namely **Propositional Logic of Knowledge and Branching Time for $n > 0$ agents Act-CTL- K_n** (Garanina, Kalinina, & Shilov, 2004; Shilov, Garanina & Choe, 2006; Shilov & Garanina, 2006). First we provide a formal definition of *Act-CTL- K_n* , then discuss some pragmatics, and then – in the next section – introduce model checking as a reasoning mechanism.

Let $[1..n]$ be a set of agents ($n > 0$), and *Act* be a finite alphabet of action symbols. Syntax of *Act-CTL- K_n* admits epistemic modalities K_i , and S_i for every $i \in [1..n]$, and branching-time constructs $A_b X$, $E_b X$, $A_b G$, $E_b G$, $A_b F$, $E_b F$, $A_b(\dots U \dots)$, and $E_b(\dots U \dots)$ for every $b \in Act$. Semantics is defined in terms of entailment in environments. An **(epistemic) environment** is a tuple $E = (D, \sim_1, \dots, \sim_n, I)$ such that $(D, \sim_1, \dots, \sim_n)$ is a model for **PLK $_n$** , and (D, I) is a model for *Act-CTL*. **Entailment relation** \models is defined by induction according to the standard definition for propositional connectives (see semantics of *EPDL*), and the above definitions of epistemic modalities and branching time constructs.

We are mostly interested in trace-based perfect recall synchronous environments generated from background finite environments. “Generated” means that possible “worlds” are runs of finite-state machine(s). There are several opportunities how to define semantics of

combined logics on runs. In particular, there are two extreme cases: **Forgetful Asynchronous Systems (FAS)** and **Synchronous systems with Perfect Recall (PRS)**. “Perfect recall” means that every agent has a log-file with all his/her observations along a run, while “forgetful” means that information of this kind is not available. “Synchronous” means that every agent can distinguish runs of different lengths, while “asynchronous” means that some runs of different lengths may be indistinguishable.

It is quite natural that in the FAS case combined logic $Act-CTL-K_n$ can express as much as it can express in the background finite system. In contrast, in the PRS case $Act-CTL-K_n$ becomes much more expressive than in the background finite environment. Importance of combined logics in the framework of trace-based semantics with synchronous perfect recall rely upon their characteristic as logics of agent’s learning or knowledge acquisition. We would like to argue this characteristic by the following single-agent⁴ Fake Coin Puzzle $FCP(N,M)$.

A set consists of $(N+1)$ enumerated coins. The last coin is a valid one. A single coin with a number in $[1..N]$ is fake, but other coins with numbers in $[1...(N+1)]$ are valid. All valid coins have the same weight that differs from the weight of the fake. Is it possible to identify the fake by balancing coins M times at most?

In $FCP(N,M)$ the agent (i.e. a person who have to solve the puzzle) does not know neither a number of the fake, nor whether it is lighter or heavier than the valid coins. Nevertheless, this number is in $[1..N]$, and the fake coin is either lighter (l) or heavier (h). The agent can make balancing queries and read balancing results after each query. Every balancing query is an action $b_{(L,R)}$ which consists in balancing of two disjoint sets of coins: with numbers $L \subseteq [1..N+1]$ on the left pan, and with numbers $R \subseteq [1..N+1]$ on the right pan, $|L| = |R|$. There are three possible balancing results: “<”, “>”, and “=”, which means that the left pan is lighter, heavier than or equal to the right pan, respectively. Of course, there are initial states (marked by ini) which represent a situation when no query has been made.

Let us summarize. The agent acts in the environment generated from a finite space $[1..N] \times \{l,h\} \times \{<, >, =, ini\}$. His/her admissible actions are balancing query

$b_{(L,R)}$ for disjoint $L, R \subseteq [1..N+1]$ with $|L| = |R|$. The only information available for the agent (i.e., which gives him/her an opportunity to distinguish states) is a balancing result. The agent should learn *fake_coin_number* from a sequence which may start from any initial state and then consists of M queries and corresponding results. Hence single agent logic $Act-CTL-K_l$ seems to be a very natural framework for expressing $FCP(N,M)$ as follows: to validate or refute whether

$$s \models_E (E_B X \dots_{M-times} \dots E_B X (\bigvee_{f \in [1..N]} K_l (fake_coin_number = f)) \dots)$$

for every initial state s , where E is a PRS environment generated from a finite space $[1..N] \times \{l,h\} \times \{<, >, =, ini\}$, and B is a balancing query $\bigcup_{L,R \subseteq [1..N+1]} b_{(L,R)}$.

FUTURE TRENDS: MODEL CHECKING FOR COMBINED LOGICS

The **model checking problem** for a combined logic ($Act-CTL-K_n$ in particular) and a class of **epistemic environments** (ex., PRS or FAS environments) is to validate or refute $s \models_E \varphi$, where E is a finitely-generated environment in the class, s is an “initial state” of the environment E , and φ is a formula of the logic. The above re-formulation of $FCP(N,M)$ is a particular example of a **model checking problem** for a formula of $Act-CTL-K_n$ and some finitely-generated perfect recall environment.

Papers (Meyden & Shilov, 1999) and (Garanina, Kalinina & Shilov, 2004) have demonstrated that if the number of agents $n > 1$, then the model checking problem in perfect recall synchronous systems is very hard or even undecidable. In particular, it has non-elementary⁵ upper and lower time bounds for $Act-CTL-K_n$. Papers (Meyden & Shilov, 1999) and (Shilov, Garanina & Choe, 2006) have suggested a tree-like data structures to make “feasible” model checking of combinations of temporal and action logics with propositional logic of knowledge PLK_n . Alternatively, (van der Hoek & Wooldridge, 2002; Lomuscio & Penczek, 2003) have suggested either to simplify language of logics to be combined, or to consider agents with “bounded” recall.

CONCLUSION

Combinations of temporal logics and logics of actions with logics of knowledge become an actual research topic due to the importance of study of interactions between knowledge and actions for reasoning about real-time multiagent systems. A comprehensive survey of logics, techniques, and results was out of scope of the article. The primary target of present article was to provide semi-formal introduction to the field of combined modal logics, discuss their utility for reasoning about multiagent systems. The emphasis has been done on model checking of trace-based knowledge-temporal specifications of perfect recall synchronous systems.

KEY TERMS

Environment: A labeled transition system that provides an interpretation for logic of knowledge, actions and time simultaneously.

Labeled Transition Systems or Kripke Model: An oriented labeled graph (infinite maybe). Nodes of the graph are called states or worlds, some of them are marked by propositional symbols that are interpreted to be valid in these nodes. Edges of the graph are marked by relational symbols that are interpreted by these edges.

Logic of Actions: A polymodal logic that associate modalities like “always” and “sometimes” with action symbols that are to be interpreted in labeled transition systems by transitions. A so-called Elementary Propositional Dynamic Logic (EPDL) is sample logic of actions.

Logic of Knowledge or Epistemic Logic: A polymodal logic that associate modalities like “know” and “suppose” with enumerated agents or groups of agents. Agents are to be interpreted in labeled transition systems by equivalence “indistinguishability” relations. A so-called Propositional Logic of Knowledge of n agents (PLK_n) is sample epistemic logic.

Logic of Time or Temporal Logic: A polymodal logic with a number of modalities that correspond to “next time”, “always”, “sometimes”, and “until” to be interpreted in labeled transition systems over discrete partial orders. For example, Linear Temporal Logic (LTL) is interpreted over linear orders.

Model Checking Problem: An algorithmic problem to validate or refute a property (presented by a formula) in a state of a model (from a class of Kripke structures). For example, model checking problem for combined logic of knowledge, actions and time in initial states of perfect recall finitely generated environments.

Multiagent System: A collection of communicating and collaborating agents, where every agent have some knowledge, intensions, enabillities, and possible actions.

Perfect Recall Synchronous Environment: An environment for modeling a behavior of a perfect recall synchronous system.

Perfect Recall Synchronous System: A multiagent system where every agent always records his/her observation at all moments of time while system runs.

Modularity in Artificial Neural Networks

Ricardo Téllez

Cecilio Angulo

Technical University of Catalonia, Spain

INTRODUCTION

The concept of modularity is a main concern for the generation of artificially intelligent systems. Modularity is an ubiquitous organization principle found everywhere in natural and artificial complex systems (Callebaut, 2005). Evidences from biological and philosophical points of view (Caelli and Wen, 1999) (Fodor, 1983), indicate that modularity is a requisite for complex intelligent behaviour. Besides, from an engineering point of view, modularity seems to be the only way for the construction of complex structures. Hence, whether complex neural programs for complex agents are desired, modularity is required.

This article introduces the concepts of modularity and module from a computational point of view, and how they apply to the generation of neural programs based on modules. Two levels, strategic and tactical, at which modularity can be implemented, are identified. How they work and how they can be combined for the generation of a completely modular controller for a neural network based agent is presented.

BACKGROUND

When designing a controller for an agent, there exists two main approaches: a single module contains all the agent's required behaviours (monolithic approach), or global behaviour is decomposed into a set of simpler sub-behaviours, each one implemented by one module (modular approach). Monolithic controllers implement on a single module all the required mappings between the agent's inputs and outputs. As an advantage, it is not required to identify required sub-behaviours nor relations between them. As a drawback, whether the complexity of the controller is high, it could be impossible at practice to design such a controller without obtaining large interferences between different parts of

it. Instead, when a modular controller is used, the global controller is designed by a group of sub-controllers, so required sub-controllers and their interactions for generating the final global output must be defined.

Despite the disadvantages of the modular approach (Boers, 1992), complex behaviour cannot be achieved without some degree of modularity (Azam, 2000). Modular controllers allow the acquisition of new knowledge without forgetting previously acquired one, which represents a big problem for monolithic controllers when the number of required knowledge rules to be learned is large (De Jong et al., 2004). They also minimize the effects of the credit assignment problem, where the learning mechanism must provide a learning signal based on the current performance of the controller. This learning signal must be used to modify the controller parameters which will improve the controller behaviour. In large controllers, it becomes difficult finding changing parameters of the controller based on the global learning signal. Modularization helps to keep small the controllers' size, minimizing the effect of the credit assignment.

Modular approaches allow for a complexity reduction of the task to be solved (De Jong et al., 2004). While in a monolithic system the optimization of variables is performed at the same time, resulting in a large optimization space, in modular systems, optimization is performed independently for each module resulting on reduced searching spaces. Modular systems are scalable, in the sense that former modules can be used for the generation of new ones when problems are more complex, or just new modules can be added to the already existing ones. It also implies that modular systems are robust, since the damage on one module results in a loss of the abilities given by that module, but the whole system is partially kept functioning. Modularity can be a solution to the problem of neural interference (Di Ferdinando et al., 2000), which is encountered in monolithic networks. This phenomenon

is produced when an already trained network loses part of its knowledge when either, it is re-trained to perform a different task, called temporal cross-talk (Jacobs et al., 1991), or two or more different tasks at the same time, the effect being called spatial cross-talk (Jacobs, 1990). Modular systems allow reusing modules in different activities, without re-implementation of the function represented on each different task (De Jong et al., 2004) (Garibay et al., 2004).

Modularity

From a computational point of view, modularity is understood as the property that some complex computational tasks have to be divided into simpler subtasks. Then, each of those simpler subtasks is performed by a specialized computational system called a module, generating the solution of the complex task from the solution of the simpler subtask modules (Azam, 2000). From a mathematical point of view, modularity is based on the idea of a system subset of variables which may be optimized independently of the other system variables (De Jong et al., 2004). In any case, the use of modularity implies that a structure exists in the problem to be solved.

In modular systems, each of the system modules operates primarily according to its own intrinsically determined principles. Modules within the whole system are tightly integrated but independent from other modules following their own implementations. They have either distinct or the same inputs, but they generate their own response. When the interactions between modules are weak and modules act independently from each other, the modular system is called nearly decomposable (Simon, 1969). Other authors have identified this type of modular systems as separable problems (Watson et al., 1998). This is by far one of the most studied types of modularity, and it can be found everywhere from business to biological systems. In nearly decomposable modular systems, the final optimal solution of a global task is obtained as a combination of the optimal solutions of the simpler ones (the modules).

However, the existence of decomposition for a problem doesn't imply that sub-problems are completely independent from each other. In fact, a system may be modular and still having interdependencies between modules. It is defined a decomposable problem as a problem that can be decomposed on other sub-prob-

lems, but the optimal solution of one of those problems depends on the optimal solution of some of the others (Watson, 2002). The resolution of such modular systems is more difficult than a typical separable modular system and it is usually treated as a monolithic one in the literature.

Module

Most of the works that use modularity, use the definition of module given by (Fodor, 1983), which is very similar to the concept of object in object-oriented programming: a module is a domain specific processing element, which is autonomous and cannot influence the internal working of other modules. A module can influence another only by its output, this is, the result of its computation. Modules do not know about a global problem to solve or global tasks to accomplish, and are specific stimulus driven. The final response of a modular system to the resolution of a global task, is given by the integration of the responses of the different modules by a especial unit. The global architecture of the system defines how this integration is performed. The integration unit must decide how to combine the outputs of the modules, to produce the final answer of the system, and it is not allowed to feed information back into the modules.

MODULAR NEURAL NETWORKS

When modularity is applied for the design of a modular neural network (MNN) based controller, three general steps are commonly observed: task decomposition, training and multi-module decision-making (Auda and Kamel, 1999). Task decomposition is about dividing the required controller into several sub-controllers, and assigning each sub-controller to one neural module. Modules should be trained either, in parallel, or in different processes following a sequence indicated by the modular design. Finally, when the modules have been prepared, a multi-module decision making strategy is implemented which indicates how all those modules should interact in order to generate the global controller response. This modularization approach can be seen as at the level of the task.

The previous general steps for modularity only apply for a modularization of nearly decomposable or separable problems. Decomposable problems, those

where strong interdependencies between modules exist, are not considered under that decomposition mechanism, and they are treated as monolithic ones. The article introduces the differentiation between two modular levels, the current modularization level, which concentrates on task sub-division, and a new modularization performed at the level of the devices or elements. Those approaches are called strategic and tactical, respectively.

Strategic and Tactical Modularity

Borrowing the concepts from game theory, strategy deals with what has to be done in a given situation in order to perform a task by dividing the global target solution into all the sub-targets required to accomplish the global one. Tactics, on the other hand, treats about how plans are going to be implemented, this means, how to use the resources available at that moment to accomplish each of those sub-targets.

It is defined strategic modularity in neural controllers as the modular approach that identifies which sub-goals are required for an agent in order to solve a global problem. Each sub-goal identified is implemented by a monolithic neural net. In contrast, tactical modularity in neural controllers is defined as the one that identifies which inputs and outputs are necessary for the implementation of a given goal, and it designs a single module for each input and output. In tactical modularity, modularization is performed at the level of the elements (any meaningful input or output of the neural controller) that are actually involved in the accomplishment of the task.

To our extent, all the research based on neural modularity and divide-and-conquer principles, focus their division at the strategic level, that is, how to divide the global problem into its sub-goals. Then, they implement each of those sub-goals by means of a single neural controller, final goal being generated by combining the outputs of those sub-goals in some sense. The current paper proposes, first, the definition of two different levels of modularity, and second, the use of tactical modularity as a new level of modularization that allocates space for decomposable modularity. It is expected that tactical modularization will be able in the generation of complex neural controllers when many inputs and outputs must be taken into account. It will be confirmed below, where the use of the two

types of modularity will be compared against monolithic approaches.

Implementing Modularity

Strategic modularity can be implemented by any of the modular approaches that already exist in the literature. See (Auda and Kamel, 1999) for a complete description. Any of the modularization methods described there is strategic, although it was not given that name, and they can, in general, be integrated with tactical modularity.

The term strategic is used for those modular approaches in order to differentiate them from the new proposed modularity.

Tactical modularity defines modularity at the level of the elements involved in the generation of a sub-goal. By elements, it is understood the inputs required to generate the sub-goal and the outputs that define the sub-goal solution. Each of those elements conform a tactical module, implemented by a simple neural network. That is, tactical modularity is implemented by designing a completely distributed controller composed of small processing modules around each of the meaningful elements of the problem.

The schematics for a tactical module is shown in Figure 1. Tactical modules are connected to its associated element, controlling it, and processing the information coming in, for input elements, or going out, for output elements. This kind of connectivity means that the processing element is the one that decides which commands must be sent to the output element, or how a value received from an input element must be interpreted. It is said that the processing element is responsible for its associated element.

In order to generate a complete answer for the sub-goal, all the tactical modules are connected each other, output of each module being sent back to all the others. By introducing this connectivity, each module is aware about what the others are doing, allowing that the different modules coordinate for the generation of a common answer, and avoiding a central coordinator. The resulting architecture shows a completely distributed MNN, where neural modules are independent but implement strong interactions with the other modules. Figure 2 shows an example of connectivity in the generation of a tactical modular neural controller for a simple system composed of two input elements and two outputs.

Figure 1. Schematics of a tactical module for one input element (left) and for one output element (right)

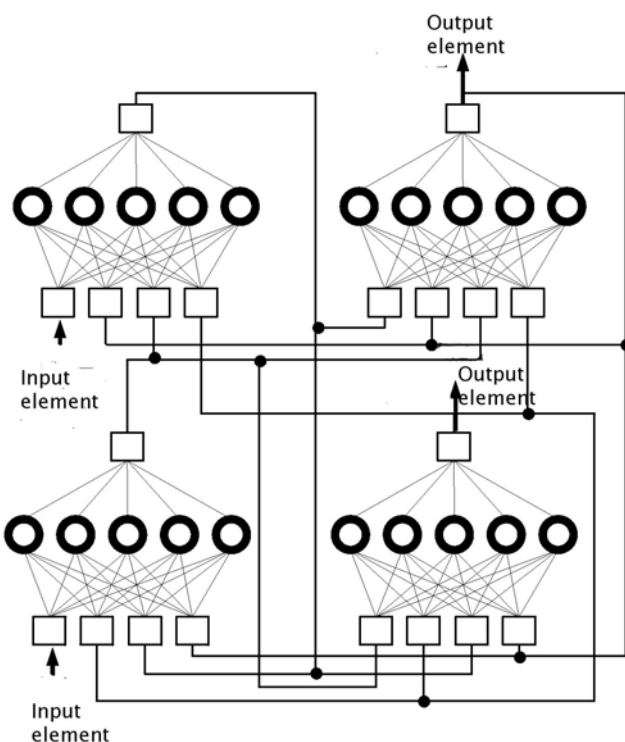

Figure 2. Connectivity of a tactical modular controller with two input elements and two output elements

Training tactical modules is difficult due to the strong relationships between the different modules. Training methods used in strategic modules based on error propagation are not suitable, so a genetic algorithm is used to train the nets, because it allows to find the networks weights without defining an error measurement, just by specifying a cost function (Di Ferdinando et al., 2000).

Combination of Different Levels

The use of one kind of modularity does not prevent, in principle, the use at the same time of the other type of modularity. In fact, strategic and tactical modularity can be used separately or in conjunction with each other. When the solution required from the controller is simple, then either, a strategic, or a tactical modularization can be used. In those cases, it is suggested that the selection of the kind of modularity be based on the complexity of the problem. For simple problems with a small number of elements, a monolithic controller will fit it. Whether the number of elements is high, then a tactical modular controller will be the best option. Finally, for very complex tasks with many elements, a combination of strategic and tactical modularization could be preferable.

When combining both levels in one neural controller, the strategic modularization should be first performed, for identifying the different sub-goals required for the implementation. Next, a tactical modularization should be completed, implementing each of those sub-goals by a group of tactical modules. The number of tactical modules for each strategic module will depend on the elements involved in the resolution of the specific sub-goal.

Application Examples

So far, strategic and tactical modularity have been mainly applied to robot control. The input elements are sensors and the output elements are actuators. In a first experiment, tactical modularity was applied to the control of a Khepera robot learning to solve the garbage collector problem (Téllez and Angulo, 2006) (Téllez and Angulo, 2007). It involved the coordination of 11 elements (seven sensors and four actuators), creating 11 tactical modules. The task was compared with different levels of modularization, including monolithic,

strategic, tactical and a combination of both. The results showed that the combination of both levels obtained the better results (see Figure 3).

On additional experiments, tactical modularity was implemented for an Aibo robot. In this case, 31 tactical modules were required to generate the controller. The controller was generated to solve different tasks like stand up, standing and pushing the ground (Téllez et al., 2005). The controller was also able to generate one of the first MNNs controller able to make Aibo walk (Téllez et al., 2006).

FUTURE TRENDS

Within the evolutionary robotics paradigm, it is very difficult to generate complex behaviours when the robot used is quite complex with a huge number of sensors and actuators. The use of tactical modularity together with strategic one, is introduced as a possible solution to the problem of generating complex behaviours in complex robots. Even if some examples have been

Figure 3. This figure represent the maximal performance value obtained by different types of modular approaches. Approach (a) is a monolithic approach, (b) and (c) are two different types of strategic approaches, (d) is tactical approach, and (f) is a reduced version of the tactical approach.

provided with a quite complex robot, it is necessary to see if the system can scale to systems with hundreds of elements.

Additional applications include its use in more classical domains like pattern recognition, speech recognition.

CONCLUSION

The level of modularity in neural controllers can be highly increased if tactical modularity is taken into account. This type of modularity complements typical modularization approaches based in strategic modularizations, by dividing strategic modules into their minimal components, and assigning one single neural module to each of them. This modularization allows the implementation of decomposable problems within a modularized structure. Both types of modularizations can be combined in order to obtain a highly modular neural controller, which shows better results in complex robot control.

KEY TERMS

Cost Function: A mathematical function used to determine how good or how bad has a neural network performed during the training phase. The cost function usually indicates what is expected from the neural controller.

Element: Any variable of the program that contains a value that is used to feed into the neural network controller (input element) or to contain the answers of the neural network (output element). The input elements are usually the variables that contain the information from which the output will be generated. The output elements contain the output of the neural controller.

Evolutionary Robotics: A technique for the creation of neural controllers for autonomous robots, based on genetic algorithms.

Genetic Algorithm: An algorithm that simulates the natural evolutionary process, applied the generation of the solution of a problem. It is usually used to obtain the value of parameters difficult to calculate by other means (like for example the neural network weights). It requires the definition of a cost function.

Modularization: A process to determine the simplest meaningful parts that compose a task. There is no formal process to implement modularization, and in practice, it is very arbitrary.

Neural Controller: It is a computer program, based on artificial neural networks. The neural controller is a neural net or group of them which act upon a series of meaningful inputs, and generates one or several outputs.

Morphological Filtering Principles

Jose Crespo

Universidad Politécnica de Madrid, Spain

INTRODUCTION

In the last fifty years, approximately, advances in computers and the availability of images in digital form have made it possible to process and to analyze them in automatic (or semi-automatic) ways. Alongside with general signal processing, the discipline of image processing has acquired a great importance for practical applications as well as for theoretical investigations. Some general image processing references are (Castleman, 1979) (Rosenfeld & Kak, 1982) (Jain, 1989) (Pratt, 1991) (Haralick & Shapiro, 1992) (Russ, 2002) (Gonzalez & Woods, 2006).

Mathematical Morphology, which was founded by Serra and Matheron in the 1960s, has distinguished itself from other types of image processing in the sense that, among other aspects, has focused on the importance of shapes. The principles of Mathematical Morphology can be found in numerous references such as (Serra, 1982) (Serra, 1988) (Giardina & Dougherty, 1988) (Schmitt & Mattioli, 1993) (Maragos & Schafer, 1990) (Heijmans, 1994) (Soille, 2003) (Dougherty & Lotufo, 2003) (Ronse, 2005).

BACKGROUND

Morphological processing especially uses set-based approaches, and it is not frequency-based. This is in fact in sharp contrast with linear signal processing (Oppenheim, Schafer, & Buck, 1999), which deals mainly with the frequency content of an input signal. Let us mention also that Mathematical Morphology (as the name suggests) normally employs a mathematical formalism.

Morphological filtering is a type of image filtering that focuses on increasing transformations. Shapes can be satisfactorily processed by morphological filters. Starting with elementary transformations that are based on Minkowski set operations, other more complex transformations can be realized. The theory of morphological filtering is soundly based on mathematics.

This article provides an overview of morphological filtering. The main families of morphological filters are discussed, taking into consideration the possibility of computing hierarchical image simplifications. Both the binary (or set) and gray-level function frameworks are considered.

In the following of this section, some fundamental notions of morphological processing are discussed. The underlying algebraic structure and associated operations, which establish the distinguishing characteristics of morphological processing, are commented.

UNDERLYING ALGEBRAIC STRUCTURE AND BASIC OPERATIONS

In morphological processing, the underlying algebraic structure is a complete *lattice* (Serra, 1988). A complete lattice is a set of elements with a partial ordering relationship, which will be denoted as \leq , and with two operations defined called *supremum* (sup) and *infimum* (inf):

- The sup operation computes the smallest element that is larger than or equal to the operands. Thus, if a, b are two elements of a lattice, " $a \sup b$ " is the element of the lattice that is larger than both a and b , and there is no smaller element that is so.
- The inf operation computes the greatest element that is smaller than or equal to the operands.

Moreover, every subset of a lattice has an infimum element and a supremum element.

For sets and gray-level images, these operations are:

- Sets (or binary images)
 - o Order relationship: \subseteq (set inclusion).
 - o " $A \sup B$ " is equal to " $A \cup B$ ", where A and B are sets.
 - o " $A \inf B$ " is equal to " $A \cap B$ ".

- Gray-level images (images with intensity values within a range of integers)

- o Order relationship: For two functions f, g :

$$f \leq g \Rightarrow f(x) \leq g(x),$$

for all pixel x

where the right-hand-side \leq refers to the order relationship of integers.

- o The sup of f and g is the function:

$$(f \sup g)(x) = \max \{f(x), g(x)\}$$

where “max” denotes the computation of the maximum of integers.

- o The inf of f and g is the function:

$$(f \inf g)(x) = \min \{f(x), g(x)\}$$

where “min” symbolizes the computation of the minimum of integers.

TRANSFORMATION PROPERTIES

The concept of ordering is key in non-linear morphological processing, which focuses especially on those transformations that preserve ordering. An *increasing* transformation Ψ defined on a lattice satisfies that, for all a, b :

$$a \leq b \Rightarrow \Psi(a) \leq \Psi(b)$$

The following two properties concern the ordering between the input and the output. If I denotes an input image, an image operator Ψ is *extensive* if and only if, $\forall I$,

$$I \leq \Psi(I)$$

A related property is the anti-extensivity property. An operator Ψ is *anti-extensive* if and only if, $\forall I$,

$$I \geq \Psi(I)$$

The concept of *idempotence* is a fundamental notion in morphological image processing. An operator Ψ is idempotent if and only if, $\forall I$,

$$\Psi(I) = \Psi \Psi(I)$$

Within the non-linear morphological framework, the important *duality* principle states that, for each morphological operator, there exists a dual one with respect to the complementation operation.

Two operators Ψ and Ω are dual if

$$\Psi = C\Omega C$$

The complementation operation C , for sets, computes the complement of the input. In the case of gray-level images a related operation is the image inversion, which inverts an image reversing the intensity values with respect to the middle point of the intensity value range.

The following concept of *pyramid* applies to multi-scale transformations. A family of operators $\{\Psi_i\}$, where $i \in S = \{1, \dots, n\}$, forms a multi-level pyramid if

$$\forall j, k \in S, j \geq k, \exists l \text{ such that } \Psi_j = \Psi_l \Psi_k$$

In words, the set of transformations $\{\Psi_i\}$ constitutes a pyramid if any level j of the hierarchy can be reached by applying a member of $\{\Psi_i\}$ to a finer (smaller index) level k .

STRUCTURING ELEMENTS

A *structuring element* is a basic tool used by morphological operators to explore and to process the shapes and forms that are present in an input image. Normally, *flat* structuring elements, which are sets that define a shape, are employed. Two usual shapes (square and diamond) are displayed next (the “x” symbol denotes the center):

(a) Square 3x3

(b) Diamond 3x3

If B denotes a structuring element, its transposed is $\bar{B} = \{(-x, -y) \in B\}$ (i.e., B inverted with respect to the coordinate origin). If a structuring element B is centered and symmetric, then $\bar{B} = B$.

DILATIONS AND EROSIONS

Dilations and *erosions* are the most basic transformations in morphological processing. Dilations δ are increasing operators that satisfy, $\forall I, I'$,

$$\delta(I \supset I') = \delta(I) \supset \delta(I')$$

Respectively, erosions ε are increasing operators that satisfy, $\forall I, I'$,

$$\varepsilon(I \inf I') = \varepsilon(I) \inf \varepsilon(I')$$

Dilations and erosions by structuring element perform, respectively, sup and inf operations over an input image that depend on a structuring element B . These dilations and erosions are symbolized, respectively, by δ_B and ε_B , and they originate from the Minkowski set addition and subtraction. Let us first discuss the set framework.

In the set framework, if A denotes an input set, the $\delta_B(A)$ dilation computes the locus of points where the B structuring element translated to has a non-empty intersection with (i.e., “touches”) input set A :

$$\delta_B(A) = \{x \mid B_x \cap A \neq \emptyset\}$$

B_x symbolizes the structuring element B translated to point (or pixel) x (i.e., $B_x = \{x' \mid x' - x \in B\}$, where “-” symbolizes the vector subtraction).

Figure 1 shows a set example in R^2 . Input set A (composed of two connected-components) and structuring element B (a circle) are displayed in part (a). The $\delta_B(A)$ dilation is shown in part (b).

The previous expression can be formulated using the sup operation as:

$$\delta_B(A) = \bigcup_{b \in B} A_{-b} = \sup_{b \in B} A_{-b}$$

Using the lattice framework, the expression for functions is formally identical to the expression for sets:

$$\delta_B(I) = \sup_{b \in B} I_{-b}$$

Note: the sup operator is that of the function lattice.

The function expression can be written in another way that gives a more operational expression to compute the value of the result of $\delta_B(I)$ at each pixel x of I :

$$[\delta_B(I)](x) = \max_{b \in B} \{I(x + b)\}$$

Figure 1. Dilation $\delta_B(A)$

(a) Set A and structuring element B

(b) $\delta_B(A)$

The sup operation has been replaced by the “max” operation that computes the maximum of a set of integers. Note that “[$\delta_B(I)$](x)” is the intensity value of pixel x in that image. The “+” symbol denotes the vector addition.

Some important properties of dilations δ_B are the following:

- For sets, dilation δ_B is commutative, i.e., if A denotes an input set, then $\delta_B(A) = \delta_A(B)$.
- If a structuring element B contains the coordinate origin, then δ_B is extensive.
- The dilation by a structuring element is associative, i.e., if B is the result of $\delta_C(D)$ (or $\delta_D(C)$), then $\delta_B(I) = \delta_C(\delta_D(I)) = \delta_D(\delta_C(I))$.

If A denotes an input set and B denotes a structuring element, the $\epsilon_B(A)$ erosion computes the locus of points where the B structuring element translated to is completely included within input set A :

$$\epsilon_B(A) = \{x \mid B_x \subseteq A\}$$

Figure 2 displays a set example of $\epsilon_B(A)$, where A is that of the previous dilation example.

The following expressions of erosions ϵ_B are analogous to those already introduced for dilations.

Figure 2. Erosion $\epsilon_B(A)$

The expression for sets formulated by means of the inf operation is:

$$\epsilon_B(A) = \bigcap_{b \in B} A_{-b} = \inf_{b \in B} A_{-b}$$

The expressions for functions are:

$$\epsilon_B(I) = \inf_{b \in B} I_{-b}$$

$$[\epsilon_B(I)](x) = \min_{b \in B} \{I(x + b)\}$$

Some important properties of erosions ϵ_B are the following:

- If the coordinate origin belongs to a structuring element B , then ϵ_B is anti-extensive.
- The erosion by a structuring element is associative, i.e., if B is the result of $\delta_C(D)$ (or $\delta_D(C)$), then $\epsilon_B(I) = \epsilon_C(\epsilon_D(I)) = \epsilon_D(\epsilon_C(I))$.

In fact, expressions for erosions are dual of, respectively, those of dilations; δ_B and ϵ_B are dual of each other:

$$\delta_B = C \epsilon_B C$$

A simple 1-D example of a gray-level dilation and erosion (where B has 3 points) is the following:

| | | | | | | | | | | | | | | | |
|---|----|----|----|----|----|----|----|----|----|----|----|---|---|---|----|
| 9 | 10 | 11 | 12 | 12 | 11 | 13 | 13 | 12 | 12 | 12 | 10 | 9 | 9 | 9 | 10 |

|---|---|----|----|----|----|----|----|----|----|----|---|---|---|---|---|

$\epsilon_B(I)$

FROM SET OPERATORS TO FUNCTION OPERATORS

Flat operators are function operators Ψ that can be derived from a set operator Ψ' that satisfy the following threshold superposition property:

$$[\Psi(I)](x) = \sup \{u : x \in \Psi'(U_u(I))\}$$

where U_u is the thresholding operator at level u , and I is an image. The thresholding operator at level u is defined as

$$U_u(I) = \{x : I(x) \geq u\}$$

Let us define a variant of the thresholding operator that outputs a binary function (instead of a set): $(U'_u(I))(x)$ is 1 if $I(x) \geq u$, and 0 otherwise. Then, a flat operator Ψ that commutes with thresholding is said to satisfy:

$$U'_u \Psi = \Psi U'_u$$

BASIC MORPHOLOGICAL FILTERS

Openings and Closings

In morphological processing, a *filter* is an increasing and idempotent transformation.

The two most fundamental filters in morphological processing arise when there is an order between the input and the filter output. They are the so-called *openings* and *closings*, symbolized, respectively, by γ and ϕ .

- An *opening* γ is an anti-extensive morphological filter.
- A *closing* ϕ is an extensive morphological filter.

The names “algebraic openings” and “algebraic closings” are also used in the literature to refer to these most general types of openings and closings.

The computation of openings and closings that use structuring elements as the “shape probes” to process input image shapes is discussed next. They are defined in terms of dilations and erosions by structuring element.

For an input set A , an opening by structuring element B , symbolized by γ_B , is the set of points x that belong to a translated structuring element that *fits* a set A , i.e., that is included in A . Let us establish how γ_B is computed in the next definition, which applies both to sets and images.

An *opening by structuring element* B , symbolized by γ_B is defined by

$$\gamma_B = \delta_{\bar{B}} \epsilon_B$$

i.e., γ_B is the sequential composition of an erosion ϵ_B followed by a dilation $\delta_{\bar{B}}$, where \bar{B} denotes B transposed.

This type of filter first erodes an input image by the ϵ_B erosion, and then the subsequent $\delta_{\bar{B}}$ dilation generally *recovers* in some sense the parts of the input image that have persisted. Nevertheless, not everything is normally recovered, and the output image is always less than or equal to the input image.

The definition of the dual closing follows. A *closing by structuring element* B , symbolized by ϕ_B is defined by

$$\phi_B = \epsilon_{\bar{B}} \delta_B$$

i.e., ϕ_B is the sequential composition of a dilation δ_B followed by an erosion $\epsilon_{\bar{B}}$, where \bar{B} denotes B transposed.

Alternated Filters

The sequential compositions of an opening γ and a closing ϕ are called *alternated* sequential compositions.

A morphological *alternated filter* is a sequential composition of an opening and a closing, i.e.,

$$\phi\gamma \text{ and } \gamma\phi,$$

are alternated filters.

An important fact is that there is generally no ordering between the input and output of alternated filters, i.e.,

$$I \not\leq \phi\gamma(I) \not\leq I$$

$$I \not\leq \gamma\phi(I) \not\leq I$$

In addition, there is generally no ordering between $\phi\gamma$ and $\gamma\phi$.

Alternated filters are quite useful in image processing and analysis because they combine in some way the effects of both openings and closings in one filter.

Parallel Combination Properties

The class of openings (or, respectively, of closings) is closed under the sup (respectively, inf) operation. In other words:

- The sup of openings is an opening.
- The inf of closings is a closing.

Different structuring elements can be combined to achieve a desired shape filtering effect. For example, the effect of a sup of openings such as $(\gamma_A \sup \gamma_B)$, which is itself an opening, can be quite different from either γ_A or γ_B .

GRANULOMETRIES AND ANTI-GRANULOMETRIES

M

The *granulometry* concept formalizes the *size distribution* notion. Size distributions are families of transformations Ψ_i with a size parameter i that satisfy the following axioms:

Figure 3. Granulometry

(a) Input image I

(b) $\gamma_4(I)$

(c) $\gamma_6(I)$

(d) $\gamma_8(I)$

- *Increasingness*
- *Anti-extensivity*
- *Absorption*

If Ψ_i, Ψ_j belong to a size distribution, where $i \leq j$, then

$$\Psi_i \Psi_j = \Psi_j \Psi_i = \Psi_{\max(i,j)}$$

In morphological filtering, the so-called *granulometries* are families of transformations that satisfy the size distribution axioms above. A family of openings $\{\gamma_i\}$, where $i \in S = \{1, \dots, n\}$ is a granulometry if, for all $i, j \in S$,

$$i \leq j \Rightarrow \gamma_i \geq \gamma_j$$

i.e., an ordered family of openings constitutes a granulometry.

The dual concept of a granulometry is called an *anti-granulometry*, which is an ordered family of closings, as defined next. A family of closings $\{\phi_i\}$, where $i \in S = \{1, \dots, n\}$ is an anti-granulometry if, for all $i, j \in S$,

$$i \leq j \Rightarrow \phi_i \leq \phi_j$$

Quite often, both a granulometry and an anti-granulometry are computed.

Normally, quantitative increasing measures are computed at each output. These measure values build a curve that can be used to characterize an input image if the measure criterion is appropriate.

$$M(\gamma_N(I)) \leq \dots \geq M(\gamma_1(I)) \leq M(I) \leq M(\phi_1(I)) \leq \dots \geq M(\phi_N(I))$$

An example of an increasing criterion is the area or number of pixels in binary images, or the volume in non-binary images.

To build a family of openings and a family of closings by structuring elements that constitute, respectively, a granulometry and antigranulometry, an appropriate family of structuring elements $\{iB / i \in \{0, \dots, N\}\}$ that ensure the ordering of openings and closings is needed. Particularly, the family of structuring elements must satisfy the following property:

$$\gamma_{(i-1)B}(iB) = iB, \text{ for } i \geq 1.$$

Figure 3 illustrates the granulometry concept. Three opening outputs have been displayed in parts (b), (c) and (d), particularly the outputs corresponding to openings γ_4, γ_6 and γ_8 , where the subindex indicates the size of the structuring element (Iñesta & Crespo, 2003). A subindex i refers to a square of side $2i+1$. There is an ordering between the four images: part (a) \geq part (b) \geq part (c) \geq part (d).

MULTI-LEVEL MORPHOLOGICAL FILTERING

Alternating Sequential Filters

Granulometries and anti-granulometries allow to build complex filters composed of ordered openings and closings.

An *alternating sequential filter* ASF is an ordered sequential composition of alternated filters $\phi_j \gamma_j$ or $\gamma_j \phi_j$, such as

$$ASF_i = \phi_i \gamma_i \dots \phi_j \gamma_j \dots \phi_1 \gamma_1$$

$$ASF'_i = \gamma_i \phi_i \dots \gamma_j \phi_j \dots \gamma_1 \phi_1$$

where $i \geq j \geq 1$, and where γ_i and ϕ_i belong, respectively, to a granulometry and an anti-granulometry.

Alternating sequential filters satisfy the following absorption property: if $i \geq j$, then

$$ASF_i ASF_j = ASF_i$$

$$ASF_j ASF_i \leq ASF_i$$

$$ASF'_i ASF'_j = ASF'_i$$

$$ASF'_j ASF'_i \geq ASF'_i$$

Morphological Pyramids

Multi-level (or multi-scale) operators are families of transformations that depend on a scale parameter i . Within morphological filters, cases that satisfy the pyramid condition are:

- granulometries,
- anti-granulometries, and
- alternating sequential filters.

FUTURE TRENDS

Operators that consider connectivity aspects have been an active research and work area in morphological processing. Connectivity integrates easily in the morphological filtering framework using the connected class concept (and the associated opening) introduced in (Serra, 1988).

The class of *connected filters* (Serra & Salembier, 1993) (Crespo, Serra, & Schafer, 1993) (Vincent, 1993) (Salembier & Serra, 1995) (Crespo, Serra, & Schafer, 1995) (Breen & Jones, 1996) (Crespo & Schafer, 1997) (Crespo & Maojo, 1998) (Garrido, Salembier, & Garcia, 1998) (Heijmans, 1999) (Crespo, Maojo, Sanandr s, Billhardt, & Mu oz, 2002) (Crespo & Maojo, 2008), which preserve shapes particularly well, has been successfully used in image processing and analysis applications. In more recent years, certain types of connected filters, such as the so-called levelings (Meyer, 1998) (Meyer, 2004), whose origin in the set framework can be traced back to (Crespo et al., 1993) (Crespo & Schafer, 1997), have been the focus of new research efforts.

CONCLUSION

This article has provided a summary of morphological filtering, which is qualitatively different from linear filtering. These differences are clear when morphological filtering is approached analysing the underlying algebraic framework and the key importance of ordering and increasingness.

Morphological filtering provides a distinctive type of image analysis that is appropriate to deal with shapes. Although in its origin morphological filtering was especially associated to set processing (and many concepts are originally set-based), it extends to non-binary gray-level functions.

KEY TERMS

Duality: The duality principle states that, for each morphological operator, there exists a dual one. In sets, the duality is established with respect to the set complementation operation (see further details in the text).

Extensivity: A transformation is extensive when its output is larger than or equal to the input. Anti-extensivity is the opposite concept: a transformation is anti-extensive when its output is smaller than or equal to the input.

Idempotence: A transformation Ψ is said to be idempotent if, when sequentially applied twice, it does not change the output of the first application, i.e., $\Psi \Psi = \Psi$.

Image Transformation: An operation that processes an input image and produces an output image.

Increasingness: A transformation is increasing when it preserves ordering. If Ψ is increasing, then $a \leq b \Rightarrow \Psi(a) \leq \Psi(b)$.

Lattice: A complete lattice is a set of elements with a partial ordering relationship and two operations called *supremum* and *infimum*.

Morphological Filter: An increasing and idempotent transformation.

Multi-Scale Transformation: A transformation that displays some characteristics controllable by means of (at least) a parameter, which is called the size or scale parameter.

MREM, Discrete Recurrent Network for Optimization

University of Málaga, Spain

INTRODUCTION

Since McCulloch and Pitts' seminal work (McCulloch & Pitts, 1943), several models of discrete neural networks have been proposed, many of them presenting the ability of assigning a discrete value (other than unipolar or bipolar) to the output of a single neuron. These models have focused on a wide variety of applications. One of the most important models was developed by J. Hopfield in (Hopfield, 1982), which has been successfully applied in fields such as pattern and image recognition and reconstruction (Sun et al., 1995), design of analog/digital circuits (Tank & Hopfield, 1986), and, above all, in combinatorial optimization (Hopfield & Tank, 1985) (Takefuji, 1992) (Takefuji & Wang, 1996), among others.

The purpose of this work is to review some applications of multivalued neural models to combinatorial optimization problems, focusing specifically on the neural model MREM, since it includes many of the multivalued models in the specialized literature.

BACKGROUND

In Hopfield and Tank's pioneering work (Hopfield & Tank, 1985), neural networks were applied for the first time to solve combinatorial optimization problems, concretely the well-known travelling salesman problem. They developed two types of networks, discrete and continuous, although the latter has been mostly chosen to solve optimization problems, adducing that it helps to escape more easily from local optima. Since then, the search for better neural algorithms, to face the diverse problems of combinatorial optimization (many of them

belonging to the class of NPcomplete problems), has been the objective of researchers in this field.

This method of optimization consists of minimizing an energy function, whose parameters and constraints are obtained by means of identification with the objective function of the optimization problem. In this case, the energy function has the form:

$$E(S) = -\frac{1}{2} \sum_{i=1}^N \sum_{j=1}^N w_{i,j} s_i s_j + \sum_{i=1}^N \theta_i s_i$$

where N is the number of neurons of the network, $w_{i,j}$ is the synaptic weight between neurons j and i , and θ_i is the threshold or bias of the neuron i .

In the discrete version of Hopfield's model, component s_i of the state vector $S = (s_1, \dots, s_N)$ can take values in $\mathcal{M} = \{-1, 1\}$ (constituting the bipolar model) or in $\mathcal{M} = \{0, 1\}$ (unipolar model). In the continuous version, $\mathcal{M} = [-1, 1]$ or $\mathcal{M} = [0, 1]$. This continuous version, although it has been traditionally the most used for optimization problems, presents certain inconveniences:

- Certain special mechanisms, maybe in form of constraints, should be contributed in order to get that, in the final state of the network, all the components of state vector S belong to $\{-1, 1\}$ or $\{0, 1\}$.
- The traditional dynamics used in this model, implemented in a digital computer, does not guarantee the decrease of the energy function in every iteration, so it is not ensured that the final state is a minimum of the energy function (Galán-Marín, 2000).

However, the biggest problem of this model (the discrete as well as the continuous one) is the possibility to converge to a non feasible state, or to a local (not global) minimum. Wilson and Pawley (1988) demonstrated, through massive simulations, that, for the travelling salesman problem of 10 cities, only 8% of the solutions were feasible, and most not good. Moreover, this proportion got worse when problem size was increased.

After this, many works were focused on improving Hopfield's network:

- By modifying the energy function (Xu & Tsai, 1991).
- By adjusting the numerous parameters present in the network, as in (Lai & Coghill, 1988).
- By using stochastic techniques in the dynamics of the network (Kirkpatrick et al., 1983) (Aarts & Korst, 1988).

Particularly, researchers tried to improve the efficiency of Hopfield's network for the travelling salesman problem, achieving acceptable results, but inferior to Operations Research techniques (Takahashi, 1997). The reason for these disappointing results is that the linear formulation used by these techniques is a great advantage in comparison with neural networks, which unavoidably use a quadratic energy function, impeding the use of subpaths deletion techniques (Smith, 1996), and provoking the appearance of a bigger number of local minima.

Another research line was devoted to the improvement of Hopfieldtype recurrent networks, and their application to diverse problems of optimization, in which some results proved to be better than those obtained by traditional Operations Research techniques (Smith & Krishnamoorthy, 1998). Takefuji's work (Takefuji, 1992) (Lee et al., 1992) (Takefuji & Wang, 1996), with a great number of publications in international media, must be highlighted. Their results have been overcome by the OCHOM model (GalánMarín & MuñozPérez, 2001).

MULTIVALUED DISCRETE RECURRENT MODEL. APPLICATION TO COMBINATORIAL OPTIMIZATION PROBLEMS

A new generalization of Hopfield's model arises in the works (MéridaCasermeiro, 2000) (MéridaCasermeiro et al., 2001), where the MREM (Multivalued REcurrent Model) model is presented.

The Neural MREM Model

This model presents two essential features that make it very versatile and that increase its applicability:

- The output of each neuron, s_i , is a value of the set $\mathcal{M} = \{m_1, m_2, \dots, m_L\}$, which is not necessarily numeric.
- The concept of similarity function f between neuron outputs is introduced. $f(x, y)$ represents the similarity between neuron states x and y .

This way, the energy function of this model is as follows:

$$E(S) = -\frac{1}{2} \sum_{i=1}^N \sum_{j=1}^N w_{i,j} f(s_i, s_j) + \sum_{i=1}^N \theta_i(s_i)$$

where $\theta_i : \mathcal{M} \rightarrow \mathbb{R}$ is a generalization of the thresholds of each neuron.

The features mentioned above make that in this model certain optimization problems (as the travelling salesman problem), have a better representation than in the unipolar or bipolar Hopfield's models, and their successors.

It is clear that MREM includes Hopfield's models (with outputs in $\mathcal{M} = \{-1, 1\}$ or in $\mathcal{M} = \{0, 1\}$) if we consider the similarity function given by the product $f(a, b) = ab$. Other multivalued models, like MAREN or SOAR (Erdem & Ozturk, 1996) (Ozturk & Abut, 1997), are also generalized by MREM.

The dynamics for this network is chosen according to the problem to be tackled.

Application to Several Combinatorial Optimization Problems

This multivalued model has been successfully applied to diverse optimization problems, outperforming the best-established algorithms. Several of these applications can be found at (MéridaCasermeiro et al., 2003) (MéridaCasermeiro & LópezRodríguez, 2005) (López-Rodríguez et al., 2006).

These problems are typical representatives of the NPcomplete complexity class, indicating their degree of difficulty in resolution.

The Travelling Salesman Problem

Traveling Salesman Problem (TSP) is one of the most wellknown and studied combinatorial optimization problems due to its wide range of reallife applications and intrinsic complexity.

Reallife applications cover aspects such as automatic routing for robots and hole location in printed circuits design (Reinelt, 1994), as well as gas turbine checking, machine task scheduling or crystallographic analysis (Bland & Shallcross, 1987), among others.

This problem can be stated as follows: given N cities X_1, \dots, X_N and distances $d_{i,j}$ between each pair of cities X_i and X_j , the objective is to find the shortest closed tour visiting each city once.

In order to get the TSP solved by this neural model, two identifications must be done:

- A network state must be identified to a solution to the TSP: Since a solution to the N cities TSP can be represented as a permutation in the set of numbers $\{1, \dots, N\}$, the net will be formed by N neurons, taking value in the set $\mathcal{M} = \{1, \dots, N\}$, such that state vector $\mathbf{S} = (s_1, \dots, s_N)$ represents a permutation of $\{1, \dots, N\}$. With this representation, $s_i = k$ means that k th city will be visited in the i th place.
- The energy function must be identified to the total distance of a tour: If we let $f(x,y) = -2d_{x,y}$ and

$$w_{i,j} = \begin{cases} 1, & (j = i+1) \vee ((i = N) \wedge (j = 1)) \\ 0, & \text{otherwise} \end{cases}$$

the energy function obtained is

$$E(\mathbf{S}) = \sum_{i=1}^{N-1} d_{s_i, s_{i+1}} + d_{s_N, s_1},$$

the total distance of the tour represented by state vector \mathbf{S} .

Computational dynamics is based on starting with a random feasible initial state vector and updating neuron outputs to keep the current state vector inside the feasible states set. To this end, at each iteration, a 2opt update will be made on current state vector, that is, every pair of neurons, p, q with $p > q + 1$, is studied and checked in parallel whether there exists a cross between segments (s_p, s_{p+1}) and (s_q, s_{q+1}) . In this case, the next relation holds:

$$d_{s_p, s_{p+1}} + d_{s_q, s_{q+1}} > d_{s_p, s_q} + d_{s_{p+1}, s_{q+1}}$$

Then, the trajectory between cities s_{p+1} and s_q is inverted, that is, if \mathbf{S} is the current state, the new state vector \mathbf{S}' will be defined by:

$$s'_i = \begin{cases} s_{q+p+1-i}, & p+1 \leq i \leq q \\ s_i, & \text{otherwise} \end{cases}$$

As an additional technique for improvement, it has also been considered 3opt updates: the tour is decomposed into three consecutive arcs, A, B and C, which are then recombined in all possible ways: $\{ABC, ACB, AB'C, ABC', AB'C', AC'B, ACB', AC'B'\}$, where A', B', C' are the reversed arcs corresponding to A, B, and C, respectively. Note that $\{ABC, AB'C, ABC', AC'B'\}$ are 2opt updates, so there is no need to check them again.

The next state of the net will be the combination that decreases most the energy function. Further details in (MéridaCasermeiro et al., 2003).

In (MéridaCasermeiro et al., 2003), some experimental results are provided, for problems from the TSPLIB repository (see Table 1). This model is compared against KNIES (Aras et al., 1999), a model based on Kohonen's self organizing map. MREM proved to outperform KNIES, obtaining in many cases almost optimal solutions.

The Graph Partition Problem

Let $\mathcal{G} = (\mathcal{V}, \varepsilon)$ be an undirected graph without self-connections. $\mathcal{V} = \{v_i\}$ is the set of vertices and ε is the set of n_e edges. For each edge $(v_i, v_j) \in \varepsilon$ there is

a weight $c_{i,j} \in \mathbb{R}^+$. All weights can be expressed by a symmetric real matrix C , with $c_{i,j} = 0$ when it does not exist the arc (v_i, v_j) .

MaxCut Problem: to find a partition of \mathcal{V} into K disjoint sets A_i such that the sum of the weights of the

edges from ε , that have their endpoints in different elements of the partition, is maximum. Therefore, the function to maximize is

$$\sum_{i|v_i \in A_m} \sum_{j|v_j \in A_n} c_{i,j} \quad m > n$$

To solve the MaxCut problem with MREM, we need N neurons, one per node in \mathcal{V} . The output of neuron i , $s_i \in \mathcal{M} = \{1, 2, \dots, K\}$, will denote that i th node is assigned to A_{s_i} .

Since it is equivalent to maximize the cost of edges cut by the partition and to minimize the cost of edges with endpoints in the same set of the partition, the objective function can be modelled as an energy

function by taking $w_{ij} = -2c_{ij}$ and $f(x,y) = \delta_{x,y}$ (that is, $f(x,y) = 1$ if, and only if, $x = y$, otherwise it is 0), considering $\theta_i = 0$.

The dynamics used in (MéridaCasermeiro & López-Rodríguez, 2005) was named best2.

best2 consists in getting the greatest decrease of the energy function by changing the state of only two neurons at each time. If neurons p and q are to be updated, energy increments $\Delta E(i,j)$ when $s_p = i$ and $s_q = j$, for $i, j \in \{1, \dots, K\}$, are computed. Then, the state of minimum increase is chosen as the new network state.

By using this dynamics, in (MéridaCasermeiro & LópezRodríguez, 2005), the MREM model is compared against some other networks, like OCHOM (Galán-Marín & MuñozPérez, 2001), obtaining the best results in authors' experiments (see Table 2).

The 2Pages Graph Layout Problem

In the last years, several graph representation problems have been studied in the literature. Most of them are related to the linear graph layout problem, in which the vertices of a graph are placed along a horizontal “node line”, or “spine” (dividing the plane into two halfplanes or “pages”) and then edges are added to this representation as specified by the adjacency matrix. The objective of this problem is to minimize the number of crossings produced by such a layout.

Some examples of problems associated to this linear graph layout problem (or 2 pages crossing number problem, 2PCNP) are the bandwidth problem (Chinn et al., 1982), the book thickness problem (Kainen, 1990), the pagenumber problem (Malitz, 1994), the boundary VLSI layout problem (Ullman, 1984) and the singlerow routing problem (Raghavan & Sahni, 1983), or printed circuit board layout (Sinden, 1966) and automated graph drawing (Tamassia et al., 1988).

In (LópezRodríguez et al., 2007), a neural model, derived from MREM, is designed to solve this problem. One of the differences of this model with the algorithms

developed in literature is that there is no need of assigning a good ordering of the vertices at a preprocessing step. The model, as well as the relative position of the arcs, computes this optimal node order.

To solve the 2PCNP problem, authors have considered two MREM neural models:

- The first network will be formed by N neurons, being N the number of nodes in the graph. Neurons output (the state vector) indicate the node ordering in the line. Thus, $s_i = k$ will be interpreted as the k th node being placed in the i th position in the node line. Hence, the output of each neuron can take value in the set $\mathcal{M}_1 = \{1, 2, \dots, N\}$.
- The second network will be formed by as many neurons as edges in the graph, M . The output of each neuron will belong to the set $\mathcal{M}_2 = \{-1, 1\}$. For the arc (v_i, v_j) , $S_{(v_i, v_j)} = -1$ will indicate that the edge will be drawn in the lower halfplane, and $S_{(v_i, v_j)} = +1$, in the upper one.

Initially, the state of the net of vertices is randomly selected as a permutation of $\{1, 2, \dots, N\}$. At any time,

Table 3. Comparison between MREM and the heuristics mentioned in Cimikowski's work

| Graph | N | M | MREM | CN | e-len | 1-page | greedy |
|----------------------|-----|-----|------|-----|-------|--------|--------|
| K_6 | 6 | 21 | 3 | 3 | 3 | 4 | 5 |

| $C_{28}(1, 3, 5)$ | 28 | 84 | 80 | 86 | 138 | 138 | 130 |
| $C_{30}(1, 3, 5)$ | 30 | 90 | 92 | 96 | 148 | 150 | 140 |

Figure 2. Optimal layouts for graphs K_6 (left) and $K_{3,3}$ (right)

the net is looking for a better solution than the current one, in terms of minimizing the energy function. This is achieved by permuting the output of two neurons (node positions) and changing the location of an edge (from the upper halfplane to the lower one, and viceversa).

In (LópezRodríguez et al., 2007), this new model is compared against some heuristics (Cimikowski, 2002) specially designed for this problem. MREM obtained the best solutions in the experiments, improving the best known solution in some cases (Table 3).

FUTURE TRENDS

Recurrent neural networks can be used to solve many optimization problems. Researchers and practitioners can benefit from the application of the neural model MREM to diverse optimization problems.

Other problems where these models can be applied cover aspects such as data classification, image compression by vector quantization, etc. It must be noted that many graph-based problems can be easily formulated in terms of minimizing the energy function of this model: degreeconstrained minimum spanning tree, maximum clique, etc.

CONCLUSION

The first works in optimization by neural networks were inspired in Hopfield's models. These models did not obtain good results when compared to the wellknown Operations Research techniques.

Many researchers focused on developing new neural models to improve the performance of Hopfieldtype networks in this kind of tasks.

The problem of these binary models is that all the information given by the problem has to be specified by means of only two values ($\{0,1\}$ or $\{-1,1\}$), so some information is lost.

Multivalued neural models are designed to represent the information of the problem by means of more than two values, achieving a better representation of the problem.

With this improvement, computational dynamics of multivalued models can be easily designed to solve a given optimization problem. These advantages make this kind of networks a very powerful ally in tackling combinatorial problems.

The MREM model is a multivalued model that generalizes many other models, so it can be easily used to solve optimization problems, as shown in the text.

Some applications of the model are wellknown NPcomplete optimization problems, like the Traveling Salesman Problem, the Graph Partition Problem, and the 2 Pages Crossing Number Problem. As shown in the references, this model is able to outperform the bestalgorithmuptodate in each of the mentioned problems.

KEY TERMS

2 Pages Graph Layout Problem: Problem of finding an ordering of the nodes of a graph on a straight line, and assigning, to each edge, a location in any of the two halfplanes induced by that line, such that the number of crossings between edges is minimum.

Artificial Neural Network: Structure for distributed and parallel processing of information, formed by a series of units (which may possess a local memory and make local information processing operations), interconnected via one-way communication channels, called connections.

Computational Dynamics: Updating scheme of the neuron outputs in a neural model.

Energy Function: Objective function of the optimization problem solved by a neural model.

MaxCut Problem: Problem of finding a partition of the set of nodes of a weighted graph, such that the sum of the costs corresponding to edges, with end-points in different sets of the partition, is maximum.

Multivalued Discrete Neural Model: A model of neural networks in which neuron outputs may take value in the set $\mathcal{M} = \{m_1, \dots, m_L\}$, instead of $\mathcal{M} = \{-1, 1\}$ or $\mathcal{M} = \{0, 1\}$.

Travelling Salesman Problem: Problem of finding the shortest closed tour that visits a series of N cities. Each city must be visited exactly one time.

Multilayer Optimization Approach for Fuzzy Systems

Ivan N. Silva

University of São Paulo, Brazil

Rogério A. Flauzino

University of São Paulo, Brazil

INTRODUCTION

The design of fuzzy inference systems comes along with several decisions taken by the designers since is necessary to determine, in a coherent way, the number of membership functions for the inputs and outputs, and also the specification of the fuzzy rules set of the system, besides defining the strategies of rules aggregation and defuzzification of output sets. The need to develop systematic procedures to assist the designers has been wide because the trial and error technique is the unique often available (Figueiredo & Gomide, 1997).

In general terms, for applications involving system identification and fuzzy modeling, it is convenient to use energy functions that express the error between the desired results and those provided by the fuzzy system. An example is the use of the mean squared error or normalized mean squared error as energy functions. In the context of systems identification, besides the mean squared error, data regularization indicators can be added to the energy function in order to improve the system response in presence of noises (from training data) (Guillaume, 2001).

In the absence of a tuning set, such as happens in parameters adjustment of a process controller, the energy function can be defined by functions that consider the desired requirements of a particular design (Wan, Hirasawa, Hu & Murata, 2001), i.e., maximum overshoot signal, setting time, rise time, undamped natural frequency, etc.

From this point of view, this article presents a new methodology based on error backpropagation for the adjustment of fuzzy inference systems, which can be then designed as a three layers model. Each one of these layers represents the tasks performed by the fuzzy inference system such as fuzzification, fuzzy rules inference and defuzzification. The adjustment

procedure proposed in this article is performed through the adaptation of its free parameters, from each one of these layers, in order to minimize the energy function previously specified.

In principle, the adjustment can be made layer by layer separately. The operational differences associated with each layer, where the parameters adjustment of a layer does not influence the performance of other, allow single adjustment of each layer. Thus, the routine of fuzzy inference system tuning acquires a larger flexibility when compared to the training process used in artificial neural networks. This methodology is interesting, not only for the results presented and obtained through computer simulations, but also for its generality concerning to the kind of fuzzy inference system used. Therefore, such methodology is expandable either to the Mandani architecture or also to that suggested by Takagi-Sugeno.

BACKGROUND

In the last years it has been observed a wide and crescent interest in applications involving logic fuzzy. These applications include from consumer products, such as cameras, video camcorders, washing machines and microwave ovens, even industrial applications as control of processes, medical instrumentation and decision support systems (Ramot, Friedman, Langholz & Kandel, 2003).

The fuzzy inference systems can be treated as methods that use the concepts and operations defined by the fuzzy set theory and by fuzzy reasoning methods (Sugeno & Yasukawa, 1993). Basically, these operational functions include fuzzification of inputs, application of inference rules, aggregation of rules and defuzzification, which represents the crisp outputs of the fuzzy

system (Jang, 1993). At present time, there are several researchers engaged in studies related to the design techniques involving fuzzy inference systems.

The first type of design technique of fuzzy inference system has its focus addressed to enable the modeling of process from their expert knowledge bases, where both antecedent and consequent terms of the rules are always fuzzy sets, offering then a high semantic level and a good interpretability capacity (Mandani & Assilian, 1975). However, the applicability of this technique in the mapping of complex systems composed by several input and output variables has been an arduous task, which can produce as inaccurate results as poor performance (Guillaume, 2001)(Becker, 1991).

The second type of design technique of fuzzy inference system can be identified as being those that incorporate learning, in an automatic way, from data that are representing the behavior of the input and output variables of the process. Therefore, this design strategy uses a collection of input and output values obtained from the process to be modeled, which differs of the first design strategy, where the fuzzy system was defined using only the expert knowledge acquired from observation on the respective system. In a generic way, the methods derived from this second strategy can be interpreted as being composed by automatic generation techniques of fuzzy rules, which use the available data for their adjustment procedures (or training).

Among the main approaches belonging to this second design strategy, it has been highlighted the ANFIS (Adaptive-Network-based Fuzzy Inference Systems) algorithm proposed by Jang (1993), which is applicable to the fuzzy architectures constituted by real polynomial functions as consequent terms of the fuzzy rules, such as those presented by Takagi & Sugeno (1985) and Sugeno & Kang (1988). The more recent approaches, such as those proposed by Panella & Gallo (2005), Huang & Babri (2006) and Li & Hori (2006), are also belonging to this design strategy.

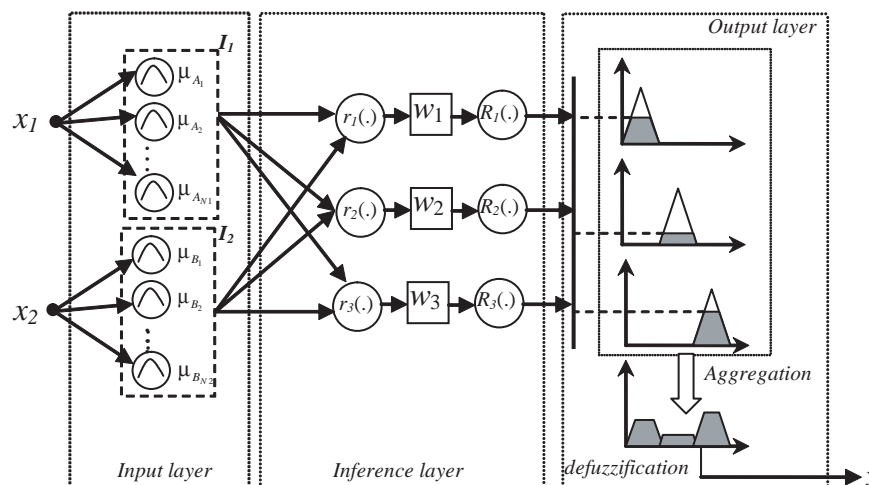

However, the representation of a process through these automatic architectures can implicate in interpretability reduction in relation to the created base of rules, whose consequent terms are expressed in most of the cases by polynomial functions, instead of linguistic variables (Kamimura, Takagi & Nakanishi, 1994).

Thus, the development of adjustment algorithms of fuzzy inference systems, which the consequent terms of the fuzzy rules are also represented by fuzzy sets, has been widely motivated.

MAIN FOCUS OF THE CHAPTER

Considering the operational functions performed by the fuzzy inference systems, it is convenient to represent them by a three-layer model. Thus, the fuzzy inference

Figure 1. Fuzzy inference system composed by two inputs and one output

system presented in this article can be represented by the sequential composition of three layers, i.e., input layer, inference layer and output layer.

The input layer has functionalities of connecting the input variables (coming from outside) with the fuzzy inference system, performing their respective fuzzifications through proper membership functions. In the inference layer of the fuzzy rules, the input fuzzified variables are combined among them, according to defined rules, using as support the operations defined by the fuzzy theory. The resulting set of this aggregation process is then defuzzified to produce the fuzzy inference system output. The aggregation and defuzzification process of the fuzzy system output are both made by the output layer. It is important to observe, concerning to the output layer, that although it performs the two processes above described, it is also responsible for storing the membership functions of the output variables. As illustration, Fig. 1 shows the proposed multilayer model, which is constituted by two inputs and one output, having three fuzzy rules in its inference layer.

In the following subsections further details will be presented about how fuzzy inference systems can be represented by a three-layers model.

Input Layer

The inputs fuzzification has the purpose of determining the membership degree of each input related to the fuzzy sets associated with each input variable. To each input variable of the fuzzy system can be associated as many fuzzy sets as necessary. In this way, let a fuzzy system constituted by only one input with N fuzzy sets, the output of the input layer will be a column vector with N elements, which are representing the membership degrees of this input in relation to those fuzzy sets. If we define the input of this fuzzy system with a unique input x , then the output of the input layer will be the vector I_I represented by:

$$I_I(x) = [\mu_{A_1}(x) \quad \mu_{A_2}(x) \quad \cdots \quad \mu_{A_N}(x)]^T \quad (1)$$

where $\mu_{A_k}(\cdot)$ is the membership function defined to input x , which is referring to the k -th fuzzy set associated with it.

The generalization of the input layer concept for a fuzzy system having p input variables can be achieved

if we consider each input being modeled as a sub-layer of the input layer. Taking into account this consideration, the output vector of the input layer $I(x)$ is then defined by:

$$I(x) = [I_1(x_1)^T \quad I_2(x_2)^T \quad \cdots \quad I_p(x_p)^T]^T \quad (2)$$

where x_i is the i -th input of the fuzzy system and $I_k(\cdot)$ is the k -th vector of membership functions associated with the input x_k . In Fig. 1 is illustrated the input layer for a fuzzy system composed by two inputs, which are mapped by the vectors I_1 and I_2 .

There are several membership functions that can be used in the proposed approach. One of the necessary requisites for those functions is that they are normalized in the closed domain $[0,1]$.

Inference Layer

The inference layer of a fuzzy system has the functionality of processing the fuzzy inference rules defined for it. Another functionality is to provide a knowledge base for the process.

In this paper, the fuzzy inference system has initially all the possible inferred rules. Therefore, the tuning algorithm has the task of weighting the inference rules. The weighting of the inference rules is a proper way to represent the most important rules, or even to allow that conflicting rules are related to each other without any linguistic completeness loss. Thus, it is possible to express the i -th fuzzy rule as follows:

$$R_i(I(x)) = w_i r_i(I(x)) \quad (3)$$

where $R_i(\cdot)$ is the function representing the fuzzy weighting of the i -th fuzzy rule, w_i is the weight of the i -th fuzzy rule and $r_i(\cdot)$ represents the fuzzy value of the i -th fuzzy rule. In Fig. 1, it is shown the composition involving $r_i(\cdot)$ and $R_i(\cdot)$ for the three fuzzy rules belonging to the inference layer.

Output Layer

The output layer of the fuzzy inference system aims to aggregate the inference rules as well as the defuzzification of the fuzzy set generated from the aggregation of these inference rules.

Besides the operational aspects, the aggregation and defuzzification methods must consider the requi-

sites of hardware performance in order to reduce the computational effort needed for processing the fuzzy system. In this paper, the output layer of the inference system is also adjusted. The adjustment of this layer occurs in a similar way to that occurred with the input layer of the fuzzy system. As example, an illustration representing the procedures involved with the output layer is also shown in Fig. 1.

Adjustment of the Fuzzy Inference System

Let a fuzzy system with two inputs, each one composed of three gaussian membership functions, with a total of five inference rules, and having an output defined by two gaussian membership functions. It is known that, for each gaussian membership function, two free parameters should be considered, i.e., the mean and the standard deviation. Consequently, the number of free parameters of the input layer is 12. For each inference rule, a weighting factor has been associated, resulting a total of 5 free parameters in the inference layer. In relation to the output layer, the same considerations used for the input layer are valid. Therefore, four free parameters are associated with the output layer.

Therefore, the mapping f between the input space x and the output space y may be defined by:

$$y = f(x, mf_{In}, w, mf_{Out}) \quad (4)$$

where mf_{In} is the parameter vector associated with the input membership functions, w is the weight vector of the inference rules, and mf_{Out} is the parameter vector associated with the output membership functions. Therefore, mf_{In} , w and mf_{Out} represent the free parameters of the fuzzy system, which can be rewritten as follows:

$$y = f(x, \Theta) \quad (5)$$

where Θ is the vector resulting from concatenation of the free parameters involved with the fuzzy system, i.e.

$$\Theta = [mf_{In}^T, w^T, mf_{Out}^T] \quad (6)$$

The energy function to be minimized, considering the fixed tuning set $\{x, d\}$, is defined by:

$$\xi \equiv \xi_{(x,y)}(\Theta) \quad (7)$$

where ξ represents the energy function associated with the fuzzy inference system f .

Unconstrained Optimization Techniques

Let an energy function $\xi_{(x,y)}(\Theta)$ differentiable in relation to free parameters of the fuzzy inference system. Thus, the objective is to find an optimum solution Θ^* subject to:

$$\xi(\Theta^*) \leq \xi(\Theta) \quad (8)$$

Therefore, we can observe that to satisfy the condition expressed in (8), it is necessary to solve an unconstrained optimization problem to obtain the solution Θ^* , which is given by:

$$\Theta^* \equiv \arg \min_{\Theta} \xi(\Theta) \quad (9)$$

The condition that expresses the optimum solution in (9) can also be rewritten as follows:

$$\nabla \xi(\Theta^*) = 0$$

where ∇ is the gradient operator defined by:

$$\nabla \xi(\Theta) = \left[\frac{\partial \xi}{\partial \Theta_1}, \frac{\partial \xi}{\partial \Theta_2}, \dots, \frac{\partial \xi}{\partial \Theta_m} \right]^T \quad (10)$$

There are several techniques used to solve unconstrained optimization problems. A detailed description of these methods can be found in Bertsekas (1999). The selection of the most proper method is related to the complexity associated with the energy function. For example, the Gauss-Newton method for unconstrained optimization can be more applicable in problems where the energy function is defined by:

$$\xi(\Theta) = \frac{1}{2} \sum_{i=1}^m e^2(i) \quad (11)$$

where $e(i)$ is the absolute error in relation to the i -th tuning pattern.

In this paper, a derivation of the Gauss-Newton method is used for tuning fuzzy inference system, which is defined by the expression following:

$$\Theta_{next} = \Theta_{now} - \frac{1}{2}(\mathbf{J}^T \mathbf{J})^{-1} \mathbf{g} \quad (12)$$

where \mathbf{g} is the gradient of ξ expressed in (11) and \mathbf{J} is the Jacobean matrix of e defined in (12). The optimization algorithm used was the Levenberg-Marquardt method (Marquardt, 1963), which can efficiently handle ill-conditioned matrices $\mathbf{J}^T \mathbf{J}$ by altering equation (13) as follows:

$$\Theta_{next} = \Theta_{now} - \frac{1}{2}(\mathbf{J}^T \mathbf{J} + \lambda \mathbf{I})^{-1} \mathbf{g} \quad (13)$$

The calculation of the matrices \mathbf{J} and the vectors \mathbf{g} were performed through the finite differences method.

Simulation Results

This section presents simulation results of the proposed methodology for the Mandani fuzzy model. In the two examples following the fuzzy system is used to model nonlinear functions. In the first example, a fuzzy inference system is used to predict the Mackey-Glass time series. In the second example, a two-dimensional *sinc* function is modeled by the fuzzy inference system.

Example 1: Modeling the Mackey-Grass Function

Using the adjustment methodology presented in this paper, a fuzzy inference system of Mandani type was developed with objective to predict the Mackey-Glass time series (Mackey & Glass, 1977), which is defined by:

$$\frac{dx(t)}{dt} = -b \cdot x(t) + \frac{a \cdot x(t - \tau)}{1 + x(t - \tau)^c} \quad (14)$$

where the values of the constants are usually assumed as $a = 0.2$, $b = 0.1$ and $c = 10$. The value for the delay constant τ was 17. The tuning set was constituted by

500 patterns. The input variables of the fuzzy inference system were four, which correspond to values $x(t - 18)$, $x(t - 12)$, $x(t - 6)$ and $x(t)$. As output variable was adopted $x(t + 6)$.

The fuzzy inference system was defined having 4 fuzzy sets attributed to each input variable and also to the output variable. A total of 64 inference rules have been used in the inference process.

The energy function of the system was defined as being the mean squared error between the desired values $x(t + 6)$ and the values $\bar{x}(t + 6)$, i.e.

$$\xi(\Theta) = \frac{1}{L} \sum_{i=1}^L [x_i(t + 6) - \bar{x}_i(t + 6)]^2 \quad (15)$$

where L is the number of data used in the tuning process ($L=500$).

After minimization of (16), the membership functions of the fuzzy inference system were adjusted as illustrated in Fig. 2.

In Fig. 3 is presented the prediction results provided by the fuzzy inference system for 1000 sample points.

The mean squared error of estimation for the proposed problem was 0.000598 with standard deviation of 0.02448. The prediction error for the 1000 sample points is shown in Fig. 4.

For comparison, it was developed a fuzzy inference system adjusted by the ANFIS (Adaptive Neural-Fuzzy Inference System). This fuzzy inference system was composed by 10 membership functions for each input, being the knowledge base constituted by 10 rules. The mean squared error of estimation for the proposed problem was 0.000165 with standard deviation of 0.0041.

Example 2: Modeling the Two-Input Sinc Function

In this example is used the proposed methodology to model a two-dimensional *sinc* function defined by:

$$z = \text{sinc}(x, y) = \frac{\sin(x) \cdot \sin(y)}{x \cdot y} \quad (16)$$

From uniformly distributed grid points into the input range $[-10, 10] \times [-10, 10]$ of (17), 225 tuning data pairs were obtained. The fuzzy inference system used here

Figure 2. Input membership functions

Fig. 3. Estimation of the fuzzy inference system for the Mackey-Glass series

Figure 4. Prediction error for the Mackey-Glass series

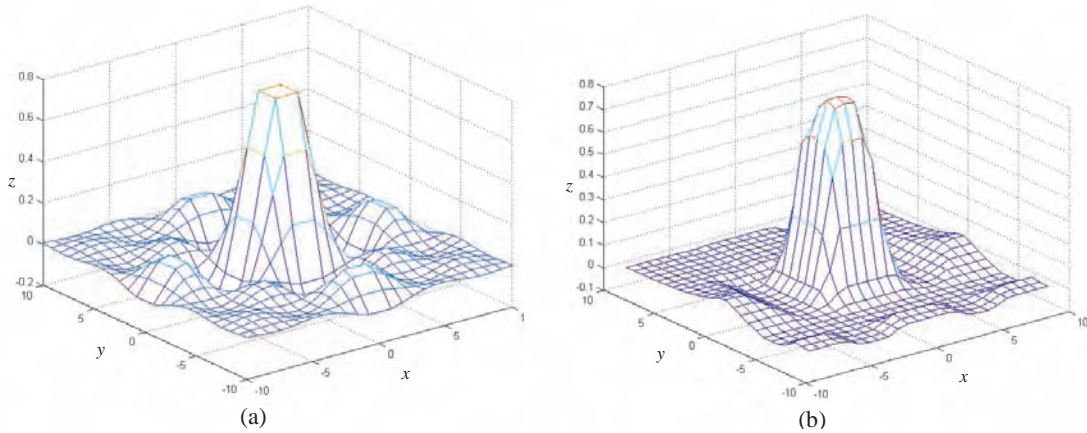

Figure 5. Tuning data (a) and reconstructed surface (b)

contains 11 rules, with 8 membership functions assigned to input variable x , 7 membership functions assigned to input y and 3 membership functions assigned to output z . The tuning data and the reconstructed surface are illustrated in Fig. 5.

FUTURE TRENDS

The methodology for the adjustment of fuzzy inference systems presented in this article can be considered very promising, not only for performance and precision obtained through computer simulations, but also for its interpretability in relation to the output variable, which is a highly desirable feature of a fuzzy system. Actually, it is the most prominent feature that distinguishes fuzzy systems from many other modeling techniques. We think that fuzzy system adjustment architectures, such as that proposed here, are ideally suited for explaining solutions to users because both premises (antecedents) and consequences of the rules are defined by fuzzy sets.

Future research and application should return to and concentrate on the linguistic features of fuzzy systems

and their capabilities for knowledge representation, exploiting the tolerance for imprecision and uncertainty to summarize data and focus on decision-relevant information.

CONCLUSION

In this article was underlined the basic foundations involved with the adjustment process of fuzzy inference systems from unconstrained optimization techniques. In order to become the more efficient tuning, it is necessary that the energy function is properly specified for the adjustment process. To validation of the proposed methodology, the results obtained by the proposed approach were compared to those provided from the ANFIS methodology, and also through of mathematical modeling problems. The results obtained from this methodology offers new perspectives of researches related to the fuzzy inference systems, allowing thus that problems previously treated only by artificial neural networks may also be treated through fuzzy inference systems.

KEY TERMS

Backpropagation Algorithm: Learning algorithm of ANNs, based on minimizing the error obtained from the comparison between the outputs that the network gives after the application of a set of network inputs and the outputs it should give (the desired outputs).

Defuzzification: Process of producing a quantifiable result (crisp) in fuzzy logic. Typically, a fuzzy system will have a number of rules that transform a number of variables into a “fuzzy” result, that is, the result is described in terms of membership in fuzzy sets.

Fuzzification: Process of transforming crisp values into grades of membership for linguistic terms of fuzzy sets. The membership function is used to associate a grade to each linguistic term.

Fuzzy Logic: Type of logic dealing with reasoning that is approximate rather than precisely deduced from classical predicate logic.

Fuzzy Rule: Linguistic constructions of type IF-THEN that have the general form “IF A THEN B ”, where A and B are (collections of) propositions containing linguistic variables.

Fuzzy System: Approach of the computational intelligence that uses a collection of fuzzy membership functions and rules, instead of Boolean logic, to reason about data.

Membership Function: Generalization of the indicator function in classical sets. In fuzzy logic, it represents the degree of truth as an extension of valuation.

Multi-Layered Semantic Data Models

László Kovács

University of Miskolc, Hungary

Tanja Sieber

University of Miskolc, Hungary

INTRODUCTION

One of the basic terms in information engineering is data. In our approach, data item is defined as representation of an information atom stored in digital computers. Although an information atom can be considered as a subject-predicate-value triplet (Lassila, 1999), data is usually given only with its value representation. This fact can lead to definitions where data is just numbers, words or pictures without context. For example in (WO, 2007), data is given as information in numerical form that can be digitally transmitted or processed. It is interesting that *we can often recognize that the term 'data' is used without any exact terminological definition with the effect that the term often remains confusing, sometimes even contradicting the definitions of the term presented. Sieber and Kammerer (2006) introduce a new interpretation of data containing several levels. The lowest level belongs to data instances that describe the form and appearance of symbols. The intermediate level is the level of representatives which includes the applied encoding system. The highest level is related to the meaning with context description. All three levels are needed to get to know the information atom. For example the symbol '36' in a database determines only the value and representation system, but not the meaning. To cover the whole information atom, the database should store some additional data items to describe the original data. The main purpose of semantic data models is to describe both context and the main structure of data items in the problem area. These additional data items are called metadata. It is important to see that:*

- metadata are data,
- metadata are relative, and
- metadata describe data.

Metadata constitute a basis for bringing together data that are related in terms of content, and for processing them further. They can be understood as a pre-requisite for intelligent and efficient administration and processing, and not least as a focused, formal means of providing relevant data.

BACKGROUND

In data management systems, the context of a value is usually defined with the help of a storage structure. An identification name (a text value) is assigned to each position of the structure. The description of storage (structure, naming and constraints) is called schema. A big problem of structural data modeling is that it can not provide all the information needed to understand the full context of the data. For example, a relational schema

RT (NM INT, KNEV CHAR(20), RU DATE)

alone is not enough to capture the meaning of the stored data items.

The main building blocks to describe the context in semantic data models (SDM) are concepts and relationships. The first widely known structure oriented semantic models in database design are the Entity-Relationship (ER) model (Chen, 1976) and the EER (Thalheim, 2000) model. The ER model consists of three basic elements: entity (concept), relationship and attribute. The attributes are considered as structure elements of the entities, one attribute may belong to only one entity. The EER model is the extension of the ER model with IS_A and HAS_A relationships. Some other extensions are SIM, IFO and RM/T. One of the main drawbacks of structure oriented SDM is the limitations of expressive power.

Later, models like UML or ODL (Catell, 1997) were developed to cover the missing object oriented elements. In the case of ODL, a class description can contain the following elements: attributes, methods, inheritance parameters, visibility, relationships and integrity rules. These models provide a powerful complexity for software engineering but they are not very flexible to describe data models of higher abstraction.

Global investigations were focused on the SDM with simpler and more universal elements. The most widely known high level semantic models are semantic networks and ontology models. A semantic network is represented with a directed graph where the vertices are the concepts and the edges are the relationships. The main differences between ontology models and the traditional SDM are in the followings: there is no fixed structural hierarchy among the concepts, flexible relationships, independence from application domain, structure is mapped into a logical formula, it can be related to an inference engine. It is widely assumed that anything at a high level of information processing must be based on ontology (Sloman, 2003). Further details can be found on current applications of ontology among others in (Taniar, 2006).

One of the first languages for ontology is RDF (Lassila, 1999). RDF is used to describe the concepts in a neutral, machine-readable format. According to the specification, the basic language elements are resources, literals and statements. There are two types of resources: entity resources and properties. A statement is a triplet (p, s, o) , where p is a property, s is a resource and o is either a literal or a resource. In another approach, p is called predicate, s is the subject and o is the object in the statement. As it can be seen, a statement corresponds to an information atom.

A pioneer representative of the next generation of languages is OWL (Bechhofer, 2004) which can be considered as an extension of RDF, that contains extra elements to describe among others typing, property characteristics, cardinality and behavioral properties. The OWL-DL language is based on Description Logic that describes the structural relationships of the domain in a logic language, which enables automatic reasoning and constraint checking in the system. The applied logic language is based on first-order predicate logic. The most widely used products related to OWL are Protégé, Pellet and KAON2.

MULTI-LAYERED SEMANTIC MODELS

Multi-Layered Schemas

In the case of systems with complex functionality, one way to reduce complexity is to build up a modular system. Modularization is a successful concept in all engineering areas. Modularization can be vertical or horizontal. Vertical modularization is called layering. The basic properties of a layered system are the followings:

- the elements are assigned to clusters (called layers);
- there exists a hierarchical relationship between the clusters;
- the relationships within the clusters differ from the relationships between the clusters;
- the clusters cooperate with each other in the role of a client or of a server.

Every layer offers a set of functionality where the functions are built upon the services of the underlying layers. In the case of a multi-layered system, the implementation can gain in cost reduction compared with a single-layer structure. Layering means modularization from the viewpoint of implementation and it has the following qualitative and quantitative benefits (Knoerschild, 2003):

- encapsulation (the layers are in great part self-contained, consistency),
- independence,
- flexibility (the layers can be replaced without affecting the other layers),
- cost reduction (simplicity in testing and in design, reusability).

The layered structure is a common technology nowadays among others in networking (Hnatyshin, 2007), image processing (Sunitha, 2007), process control (Zender, 2007) and software development (Kreku, 2006).

Multi-Layered Nature of Human Recognition

It was realized very early that human spatial cognition is based on a partially hierarchical conceptual view of space (McNamara, 1986). It is usual to perform the mapping of spatial environment with a semantic hierarchy (Kuipers, 2000). In the proposal of Sloman (2003), the internal representation of the spatial environment is implemented with a three-layered model. The lowest layer is called metric layer. It establishes an absolute frame of reference. It consists of a navigation graph that describes the important positions of the environment. In the next, topological layer, the navigational nodes are mapped into areas, where an area corresponds to a set of connected nodes. An area denotes a compound spatial concept. The highest level belongs to the conceptual layer. In this layer the areas are mapped to general abstract concepts. This level corresponds to the ontology layer that provides different relationships and a reasoning engine.

According to the current H-Cogaff view of human information processing architecture (Sloman, 2003) the cognition system consists of several regions performing concurrent activities. The regions are structured into hierarchies. The perception hierarchy can activate for example different concepts at the same time for a single sensor input image. Visual perception can detect different levels of structure and different levels of concepts. The developed multi-layer ontology model consists of three layers: the reactive, the deliberate and the meta-management layer.

Also in artificial intelligence, the application of multi-layered structures has gained a larger popularity. In (Kamimura, 2003), the information theoretical competitive learning method was implemented with multi-layered networks to solve complex problems. Networks are composed of several competitive layers. In each competitive layer, information is maximized. This successive information maximization enables networks to extract features gradually. Experimental results confirmed that information can be maximized in multi-layered networks, and the networks can extract features that cannot be detected by single-layered networks

Multi-Layered Concept Models

Traditional SDM models were intended to manage only single-layer structure. Neither of the original versions of ER, RDF or OWL uses layers in the model. On the other hand, it can be seen, that the layered structure has a lot of benefits:

- increase in simplicity of management,
- decrease in complexity,
- increase in flexibility, and
- increase in reusability.

The first classic layered models for semantic networks were developed in the 80's. The strong influence of psychological theories in human cognition can be easily observed in the proposed models. The layered model of Thompson (1990) consists of five layers similar in Greenwald's (1988) model. The base layer represents sensor data (images, sounds, signs) and the temporal relationships between these data items. The next layer is devoted to basic concepts. The connection of a concept and of its sensory appearances may vary and may be very complex (transformations). This connection should perform more complex activity than just simple association. The next level is called the level of events. In this layer, the simple object instances are bound to series and sentences. This layer should contain the logic supporting ideas of time and causality. The next level generates abstract objects that cluster object instances together. The next model level describes the activities on the abstract concepts like planning and modeling. The highest level is related to the abstract concepts and abstract activities like reasoning and metadata management.

In the proposal of Khosla (2004), the layering of ontology is strongly correlated with the functional layering of the system. The paper describes the structure of a general soft-computing module. The most internal layer is the object layer to describe the data schema. On the top of the data layer are the distributed agent layer, the tool agent layer and the optimization agent layer. These layers perform among others preprocessing, transformation and decision making. The concept of multi-layering can be applied to the traditional data models, too. A layered UML model is represented

among others in (Kreku, 2006). The layers here also correspond to the different functional areas within the application. The three proposed layers are the component layer, the HW architecture layer and the platform architecture layer.

In (Sunitha, 2007), the investigation is focused on the SDM part only. The semantic data model is divided into three layers. The bottom part is the concept measure layer that contains the descriptions of the concepts themselves. The middle layer is used to store the relationships (like specialization, classification) among the concepts. The top layer is for the context-related knowledge elements describing the environment of the application field.

In some other proposals, layering refers not to the functional structure but to the abstraction levels. In the classical UML (Terrasse, 2001), a four-layered metamodel architecture is used. The bottom layer is the object layer and the next layer is the model layer. On the top of the model layer is the metamodel layer. At the top, the meta-metamodel layer can be found. The metaobject facility (MOF) model is based on a layered, conceptual metamodel structure. The content of a conceptual layer describes the elements in the next layer down. Both UML and MOF are based on class oriented representations. In (Melnik, 2000), a three-layer abstraction model is defined for the semantic web. These layers are the syntax layer, the object layer and the semantic layer.

The semantic data model presented in (Sieber, 2006) was invented as a model for bridging the gap between data and semiotics in terms of Peirce with a special focus on technical documentation processes. The concerned knowledge can be shared between many people in different departments, different production locations (including different countries) and in different applications. As a consequence of this, in such a process nearly everyone has two roles: one of owning and dating knowledge; and one of searching and needing dated knowledge. For mathematical purposes this model was extended (Sieber, 2007) using a semantic network based upon a lattice of concepts. The result is a multi-layer semantic data model that can be used to visualize more general decoding and encoding processing between signals and (semantic) concepts.

FUTURE TRENDS

The term of layered ontology occurs very rarely in the literature. The main reason for this is that the basic ontology can describe any levels of abstractions. Thus a single layer can cover any levels of concepts. This monolithic structure will cause difficulties in integrating existing ontologies, as the overlap of concepts is harder to detect. The current research projects on ontology are usually aimed at the development of accurate ontologies for the different application domains. The main current areas are: medical systems, geographical systems, linguistics, social studies, enterprise information systems, logic, knowledge representation and automatic reasoning. Very few proposals deal with the application of modular, multi-layered ontologies. In (Purao, 2005), for example a database design specific domain is analyzed, where three layers are defined: the core (local) level, the neighborhood level and the global domain level.

Although the importance of a domain independent ontology is visible and clear for everybody, the current works seem to neglect this requirement. According to (Mikroyannidis, 2006), ontology management in most information systems is based on simplicity, ontology layering is rarely used, and the requirements for ontology evolution and integration are usually neglected. We can predict that the modularized, layered ontology models will get more attention in the near future.

CONCLUSION

Traditional semantic models are based on a single-layer structure. This approach is a drawback in the development of complex systems. As the model of human cognition is built on a multi-layer approach, and the goal of semantic models is to describe concepts of our world, the multi-layer models seem to be more accurate to create a global semantic model. The current semantic models, like UML or ontology provide some layering possibilities, but the detailed analysis of multi-layered semantic models is a task of the future.

KEY TERMS

Data Model: A formal description language to describe and to manipulate the investigated data instances. It contains three components: a static structural part, an integrity part and a manipulation part.

Multi-Layered Data Model: A data model where the model elements are assigned to levels. In the model, a hierarchy is defined between the levels. Regarding the element-level relationships, the intra-level relationships differ from the inter-level relationships.

Ontology: A semantic data model that describes the concepts and their relationships. It contains a controlled vocabulary and a grammar for using the vocabulary terms. The ontology enables to make queries and asser-

tions and reasoning. The most popular form to describe ontology is RDF and OWL.

OWL: A language to describe Web ontologies. It uses an XML format and it contains a formal description logic component, too. It provides the following extra functionality: classification, type and cardinality constraints, thesauri, decidability.

RDF: A semantic data model that describes the world with statements. A statement is a triplet having the following form: subject-predicate-object.

Semantic Data Model: A high level data model. It is usually based on concepts and it uses a graphical formalism. It contains only the key, the semantic properties of the data structure. It does not cover the details of the implementation.

UML: A standardized general-purpose modeling language for object oriented software systems. It has a graphical notation and contains several diagrams: structure diagrams (class, object, component, package) and behavioral diagrams (activity, use-case, state machine, interaction).

Multilogistic Regression by Product Units

INTRODUCTION

Multi-class pattern recognition has a wide range of applications including handwritten digit recognition (Chiang, 1998), speech tagging and recognition (Athanaselis, Bakamidis, Dologlou, Cowie, Douglas-Cowie & Cox, 2005), bioinformatics (Mahony, Benos, Smith & Golden, 2006) and text categorization (Massey, 2003). This chapter presents a comprehensive and competitive study in multi-class neural learning which combines different elements, such as multilogistic regression, neural networks and evolutionary algorithms.

The Logistic Regression model (LR) has been widely used in statistics for many years and has recently been the object of extensive study in the machine learning community. Although logistic regression is a simple and useful procedure, it poses problems when is applied to a real-problem of classification, where frequently we cannot make the stringent assumption of additive and purely linear effects of the covariates. A technique to overcome these difficulties is to augment/replace the input vector with new variables, basis functions, which are transformations of the input variables, and then to use linear models in this new space of derived input features. Methods like sigmoidal feed-forward neural networks (Bishop, 1995), generalized additive models (Hastie & Tibshirani, 1990), and PolyMARS (Koopberg, Bose & Stone, 1997), which is a hybrid of Multivariate Adaptive Regression Splines (MARS) (Friedman, 1991) specifically designed to handle classification problems, can all be seen as different non-linear basis function models. The major drawback of these approaches is stating the typology and the optimal number of the corresponding basis functions.

Logistic regression models are usually fit by maximum likelihood, where the Newton-Raphson algorithm is the traditional way to estimate the maximum likelihood a-posteriori parameters. Typically, the algorithm converges, since the log-likelihood is concave. It is important to point out that the computation of the Newton-Raphson algorithm becomes prohibitive when the number of variables is large.

Product Unit Neural Networks, PUNN, introduced by Durbin and Rumelhart (Durbin & Rumelhart, 1989), are an alternative to standard sigmoidal neural networks and are based on multiplicative nodes instead of additive ones.

BACKGROUND

In the classification problem, measurements x_i , $i = 1, 2, \dots, k$, are taken on a single individual (or object), and the individuals are to be classified into one of J classes on the basis of these measurements. It is assumed that J is finite, and the measurements x_i are random observations from these classes. A training sample $D = \{(\mathbf{x}_n, \mathbf{y}_n); n = 1, 2, \dots, N\}$ is available, where $\mathbf{x}_n = (x_{1n}, \dots, x_{kn})$ is the vector of measurements taking values in $\Omega \subset \mathbb{R}^k$, and \mathbf{y}_n is the class level of the n th individual. In this chapter, we will adopt the common technique of representing the class levels using a “1-of- J ” encoding vector $\mathbf{y} = (y^{(1)}, y^{(2)}, \dots, y^{(J)})$, such as $y^{(l)} = 1$ if \mathbf{x} corresponds to an example belonging to class l and $y^{(l)} = 0$ otherwise. Based on the training sample, we wish to find a decision function $C : \Omega \rightarrow \{1, 2, \dots, J\}$ for classifying the individuals. In other words, C provides a partition, say D_1, D_2, \dots, D_J , of Ω , where D_l corresponds to the l th class, $l = 1, 2, \dots, J$.

and measurements belonging to D_l will be classified as coming from the l th class. A misclassification occurs when a decision rule C assigns an individual (based on measurements vector) to a class j when it is actually coming from a class $l \neq j$.

To evaluate the performance of the classifiers we can define the Correctly Classified Rate by

$$CCR = \frac{1}{N} \sum_{n=1}^N I(C(\mathbf{x}_n) = \mathbf{y}_n),$$

where $I(\cdot)$ is the zero-one loss function. A good classifier tries to achieve the highest possible CCR in a given problem.

Suppose that the conditional probability that \mathbf{x} belongs to class l verifies:

$$p(y^{(l)} = 1 | \mathbf{x}) > 0, \quad l = 1, 2, \dots, J, \quad \mathbf{x} \in \Omega,$$

and set the function:

$$f_l(\mathbf{x}, \theta_l) = \log \frac{p(y^{(l)} = 1 | \mathbf{x})}{p(y^{(j)} = 1 | \mathbf{x})}, \quad l = 1, 2, \dots, J, \quad \mathbf{x} \in \Omega$$

where θ_l is the weight vector corresponding to class l and $f_j(\mathbf{x}, \theta_j) \equiv 0$. Under a multinomial logistic regression, the probability that \mathbf{x} belongs to class l is then given by

$$p(y^{(l)} = 1 | \mathbf{x}, \theta) = \frac{\exp f_l(\mathbf{x}, \theta_l)}{\sum_{j=1}^J \exp f_j(\mathbf{x}, \theta_j)}, \quad l = 1, 2, \dots, J$$

where $\theta = (\theta_1, \theta_2, \dots, \theta_{J-1})$.

The classification rule coincides with the optimal Bayes' rule. In other words, an individual should be assigned to the class which has the maximum probability, given the vector measurement \mathbf{x} :

$$C(\mathbf{x}) = \hat{l},$$

where

$$\hat{l} = \arg \max_l f_l(\mathbf{x}, \hat{\theta}_l), \quad \text{for } l = 1, \dots, J.$$

On the other hand, because of the normalization condition we have:

$$\sum_{l=1}^J p(y^{(l)} = 1 | \mathbf{x}, \theta) = 1,$$

and the probability for one of the classes (in the proposed case, the last) need not be estimated (observe that we have considered $f_j(\mathbf{x}, \theta_j) \equiv 0$).

MULTILOGISTIC REGRESSION AND PRODUCT UNIT NEURAL NETWORKS

Multilogistic Regression by using Linear and Product-Unit models (MLRPU) overcomes the nonlinear effects of the covariates by proposing a multilogistic regression model based on the combination of linear and product-unit models, where the nonlinear basis functions of the model are given by the product of the inputs raised to arbitrary powers. These basis functions express the possible strong interactions between the covariates, where the exponents are not fixed and may even take real values. In fitting the proposed model, the non-linearity of the PUNN implies that the corresponding Hessian matrix is generally indefinite and the likelihood has more local maximum. This reason justifies the use of an alternative heuristic procedure to estimate the parameters of the model.

Non-Linear Model Proposed

The general expression of the proposed model is given by:

$$f_l(\mathbf{x}, \theta_l) = \alpha_0^l + \sum_{i=1}^k \alpha_i^l x_i + \sum_{j=1}^m \beta_j^l \prod_{i=1}^k x_i^{w_{ji}}, \quad l = 1, 2, \dots, J-1$$

where

$$\theta_l = (\alpha^l, \beta^l, \mathbf{W}),$$

$$\alpha^l = (\alpha_0^l, \alpha_1^l, \dots, \alpha_k^l),$$

$$\beta^l = (\beta_1^l, \dots, \beta_m^l) \text{ and}$$

$$\mathbf{W} = (\mathbf{w}_1, \mathbf{w}_2, \dots, \mathbf{w}_m),$$

with $\mathbf{w}_j = (w_{j1}, w_{j2}, \dots, w_{jk})$,

$w_{ji} \in \mathbb{R}$.

As has been stated before, the nonlinear part of $f_i(\mathbf{x}, \boldsymbol{\theta}_i)$ corresponds to Product Unit Neural Networks (PUNN), introduced by Durbin and Rumelhart (Durbin & Rumelhart, 1989) and subsequently developed by other authors (Janson & Frenzel, 1993), (Leerink, Giles, Horne & Jabri, 1995), (Ismail & Engelbrecht, 2000), (Martínez-Estudillo, Hervás-Martínez, Martínez-Estudillo & García-Pedrajas, 2006), (Martínez-Estudillo, Martínez-Estudillo, Hervás-Martínez & García-Pedrajas, 2006). Advantages of product-unit based neural networks include increased information capacity and the ability to form higher-order combinations of inputs. They are universal approximators and it is possible to obtain upper bounds of the VC dimension of product unit neural networks that are similar to those obtained for sigmoidal neural networks (Schmitt, 2001). Despite these obvious advantages, product-unit based neural networks have a major drawback. Their training is more difficult than the training of standard sigmoidal based networks (Durbin & Rumelhart, 1989). The main reason for this difficulty is that small changes in the exponents can cause large changes in the total error surface. Hence, networks based on product units have more local minima and a greater probability of becoming trapped in them. It is well-known (Janson & Frenzel, 1993) that back-propagation is not efficient in training product-units. Several efforts have been made to develop learning methods for product units (Leerink, Giles, Horne & Jabri, 1995), (Martínez-Estudillo, Martínez-Estudillo, Hervás-Martínez, & García-Pedrajas, 2006), mainly in a regression context.

Estimation of the Model Coefficients

In the supervised learning context, the components of the weight vectors $\boldsymbol{\theta} = (\boldsymbol{\theta}_1, \boldsymbol{\theta}_2, \dots, \boldsymbol{\theta}_{j-1})$ are estimated from the training dataset D . To perform the maximum likelihood (ML) estimation of $\boldsymbol{\theta}$, one can minimize the negative log-likelihood function

$$L(\boldsymbol{\theta}) = -\frac{1}{N} \sum_{n=1}^N \log p(\mathbf{y}_n | \mathbf{x}_n, \boldsymbol{\theta}) =$$

$$= \frac{1}{N} \sum_{n=1}^N \left[-\sum_{l=1}^J y_n^{(l)} f_l(\mathbf{x}_n, \boldsymbol{\theta}_l) + \log \sum_{l=1}^J \exp f_l(\mathbf{x}_n, \boldsymbol{\theta}_l) \right]$$

The error surface associated with the proposed model is very convoluted with numerous local optima. The non-linearity of the model with respect to the parameters $\boldsymbol{\theta}_l$ and the indefinite character of the associated Hessian matrix do not recommend the use of gradient-based methods to maximize the log-likelihood function. Moreover, the optimal number of basis functions of the model (i.e. the number of hidden nodes in the product-unit neural network) is unknown. Thus, the estimation of the vector parameter $\hat{\boldsymbol{\theta}}$ is carried out by means a hybrid procedure described below.

In this paragraph we make a detailed description of the different aspects of the MLRPU methodology. The process is structured in four steps:

Step 1. We apply an evolutionary neural network algorithm to find the basis functions

$$B(\mathbf{x}, \hat{\mathbf{W}}) = \{B_1(\mathbf{x}, \hat{\mathbf{w}}_1), B_2(\mathbf{x}, \hat{\mathbf{w}}_2), \dots, B_m(\mathbf{x}, \hat{\mathbf{w}}_m)\}$$

corresponding to the nonlinear part of $f(\mathbf{x}, \boldsymbol{\theta})$. We have to determine the number of basis functions m and the weight vector $\mathbf{W} = (\mathbf{w}_1, \mathbf{w}_2, \dots, \mathbf{w}_m)$.

To apply evolutionary neural network techniques, we consider a PUNN with the following structure (Fig. 1): an input layer with a node for every input variable, a hidden layer with several nodes, and an output layer with one node for each category. The activation function of the j -th node in the hidden layer is given by

$$B_j(\mathbf{x}, \mathbf{w}_j) = \prod_{i=1}^k x_i^{w_{ji}}$$

where w_{ji} is the weight of the connection between input node i and hidden node j and $\mathbf{w}_j = (w_{j1}, \dots, w_{jk})$. The activation function of the output node l is given by

$$g_l(\mathbf{x}, \boldsymbol{\beta}^l, \boldsymbol{\Omega}) = \beta_0^l + \sum_{j=1}^m \beta_j^l B_j(\boldsymbol{\xi}, \boldsymbol{\omega}_j),$$

where β_j^l is the weight of the connection between the hidden node j and the output node l . The transfer function of all output nodes is the identity function.

The weight vector $\mathbf{W} = (\mathbf{w}_1, \mathbf{w}_2, \dots, \mathbf{w}_m)$ is estimated by means of an evolutionary programming algorithm detailed in (Hervás-Martínez, Martínez-Estudillo & Gutiérrez, 2006), that optimizes the error function

Figure 1. Model of a product-unit based neural network

given by the negative log-likelihood for N observations associated with the product-unit model:

$$L^*(\boldsymbol{\beta}, \mathbf{W}) = \frac{1}{N} \sum_{n=1}^N \left[-\sum_{l=1}^{J-1} y_n^{(l)} g_l(\mathbf{x}_n, \boldsymbol{\beta}^l, \mathbf{W}) + \log \sum_{l=1}^{J-1} \exp g_l(\mathbf{x}_n, \boldsymbol{\beta}^l, \mathbf{W}) \right]$$

Although in this step the evolutionary process obtains a concrete value for the $\boldsymbol{\beta}$ vector, we only consider the estimated weight vector $\hat{\mathbf{W}} = (\hat{\mathbf{w}}_1, \hat{\mathbf{w}}_2, \dots, \hat{\mathbf{w}}_m)$ that builds the basis functions. The value for the $\boldsymbol{\beta}$ vector will be determined in Step 3 together with the $\boldsymbol{\alpha}$ coefficient vector.

Step 2. We consider the following transformation of the input space by adding the nonlinear basis functions obtained by the evolutionary algorithm in step 1:

$$H: \mathbb{R}^k \rightarrow \mathbb{R}^{k+m}$$

$$(x_1, x_2, \dots, x_k) \rightarrow (x_1, x_2, \dots, x_k, z_1, \dots, z_m)$$

$$\text{where } z_l = B_l(\mathbf{x}, \hat{\mathbf{w}}_1), \dots, z_m = B_m(\mathbf{x}, \hat{\mathbf{w}}_m).$$

Step 3. We minimize the negative log-likelihood function for N observations:

$$L(\boldsymbol{\alpha}, \boldsymbol{\beta}) = \frac{1}{N} \sum_{n=1}^N \left[-\sum_{l=1}^J y_n^{(l)} (\boldsymbol{\alpha}^l \mathbf{x}_n + \boldsymbol{\beta}^l \mathbf{z}_n) + \log \sum_{l=1}^J \exp(\boldsymbol{\alpha}^l \mathbf{x}_n + \boldsymbol{\beta}^l \mathbf{z}_n) \right]$$

where $\mathbf{x}_n = (1, x_{1n}, \dots, x_{kn})$. Now, the Hessian matrix of the negative log-likelihood in the new variables $x_1, x_2, \dots, x_k, z_1, \dots, z_m$ is semidefinite positive. Then, we could apply Newton's method, also known, in this case, as Iteratively Reweighted Least Squares (IRLS). Although there are other methods for performing this optimization, none clearly outperforms IRLS (Minka, 2003). The estimated vector coefficient $\hat{\boldsymbol{\theta}} = (\hat{\boldsymbol{\alpha}}, \hat{\boldsymbol{\beta}}, \hat{\mathbf{W}})$ determines the model:

$$f_l(\mathbf{x}, \hat{\boldsymbol{\theta}}) = \hat{\alpha}_0^l + \sum_{i=1}^k \hat{\alpha}_i^l x_i + \sum_{j=1}^m \hat{\beta}_j^l \prod_{i=1}^k x_i^{\hat{w}_{ji}},$$

$$l = 1, 2, \dots, J-1$$

Step 4. In order to select the final model, we use a backward stepwise procedure, starting with the full model with all the covariates, initial and PU covariates, and successively prune variables sequentially to the model until further pruning does not improve the fit.

Application to Remote Sensing

We have tested the proposed methodology in a real agronomical problem of precision farming, consisting of mapping weed patches in crop fields, through remote sensed data.

Remote sensing systems can provide a large amount of continuous field information at a reasonable cost. Remote sensed imagery shows great potential in modeling different agronomic parameters for its application in precision farming. One aspect of overcoming the possibility of minimizing the impact of agriculture on environmental quality is the development of more efficient approaches for crop production determination and for site-specific weed management. Potential economic and environmental benefits of site-specific herbicide applications include reduced spray volume, herbicide costs and non-target spraying, and increased control of weeds, (Thompson, Stafford & Miller, 1991), (Medlin, Shaw, Gerard, & LaMastus, 2000).

We face a mapping weed patches problem through the analysis of aerial photographs. Images and data sets have been given by the Precision Farming and Remote Sensing Unit of the Department of Crop Protection, Institute of Sustainable Agriculture (CSIC, Spain), whose members reported previous results in predicting *Ridolfia segetum* Moris patches, (Peña-Barragán, López-Granados, Jurado-Expósito & García-Torres, 2007). The data analyzed correspond to a study conducted in 2003 at the 42 ha-farm Matabueyes, naturally infested by *R. segetum*. At a field study, the nature of 2,400 pixels was determined, being them considered as ground-truth pixels: 800 pixels were classified as *R. segetum* and 800 pixels were classified as *R. segetum* free pixels.

Input variables include the digital values of all bands in each available image, that is: Red (R), Green (G) and Blue (B), for June image, and R, G, B and Near Infrared (NIR) for May and July images. The experimental design was conducted using a stratified holdout cross-validation procedure, where the size of training set was approximately $0.7n$ (1,120 pixels) for

the training set and $0.3n$ (480 pixels) for the generalization set, n being the size of the full dataset.

In all experiments, the EA has been applied with the same parameters. SPSS 13.0 software (SPSS, 2005) was used for applying IRLS algorithm and in order to select the more significant variables in the final model, through a backward stepwise procedure.

The models compared in the different experiments are the following: firstly, we extract the best PUNN model of the EA (EPUNN); secondly, we obtain standard Logistic Regression model using initial covariables (LR); finally, we apply Logistic Regression only over basic function extracted from EPUNN model (MLRPU) and over the same basic functions together with initial covariables (MLRLPU).

Results

Performance of each model has been evaluated using the Correctly Classified Ratio in the generalization set (CCR_G). In Table 1 we show the matrix results of classification over train and generalization sets for the three classification problems and the four models proposed (one problem at each date, May, June and July, and four models, EPUNN, LR, MLRPU and MLRLPU). Best CCR_G results are obtained with MLRPU and MLRLPU at May and June, although at July EPUNN model yields the best results. At all dates, differences between standard LR and hybrid LR (MLRPU and MLRLPU) are very significant. Table 2 includes models obtained at the date that leads to better classification results, that is, at June.

Using these models we can obtain the probability of *R. segetum* presence at all pixels of the image, including non ground-truth pixels. Figure 1, 2, 3 and 4 represents weed maps obtained using the four proposed models at June, EPUNN, LR, MLRPU and MLRLPU, respectively. Weed presence probability has been represented using a scale between white (minimum probability, nearly 0) and dark green (maximum probability, nearly 1). From these maps, the agronomical expert can decide what threshold probability value consider to apply herbicide. MLRLPU and MLRPU models clearly differentiate better between high weed density zones and weed free zones, so they have a higher interest from the point of view of intelligent site-specific herbicide application.

Table 1. Classification matrixes ($Y=0$, *R.segetum* absence; $Y=1$, *R.segetum* presence) at all dates, using best Evolutionary Product Unit Neural Network, EPUNN, Logistic Regression, LR (in italic), Logistic Regression only with Product Units, MLRPU, (in brackets), and Logistic Regression with initial covariables and Product Units, MLRLPU (in squared brackets)

FUTURE TRENDS

Concepts exposed in this chapter offer the possibility of developing new models of multi-class generalized linear regression, by means of considering different types of basis functions (Sigmoidal Units, Radial Basis

Functions and Product Units) for the non-linear part of the proposed model. Moreover, future research could include ordinal logistic regression models with different basis functions or probit models with different basis functions.

CONCLUSION

To the best of our knowledge, the approach presented in this paper is a study in multi-class neural learning which combines three tools used in machine learning research: the logistic regression, the product-unit neural network model and the evolutionary neural network paradigm. Logistic regression is a well-tested statistical approach that performs well in two-class classification and can naturally be generalized to the multi-class case. On the other hand, product-unit neural network models are an alternative to standard sigmoidal neural networks with the ability to capture non-linear interaction between the input variables. Finally, evolutionary artificial neural networks present an interesting platform for optimizing both network performance and architecture simultaneously. The adequate combination of these three elements carried out in several steps in our proposal, provides a competitive methodology to solve classification problems.

KEY TERMS

Artificial Neural Networks: A network of many simple processors (“units” or “neurons”) that imitates a biological neural network. The units are connected by unidirectional communication channels, which carry numeric data. Neural networks can be trained to find nonlinear relationships in data, and are used in applications such as robotics, speech recognition, signal processing or medical diagnosis.

Evolutionary Computation: Computation based on iterative progress, such as growth or development in a population. This population is selected in a guided random search using parallel processing to achieve the desired solution. Such processes are often inspired by biological mechanisms of evolution.

Evolutionary Programming: One of the four major evolutionary algorithm paradigms, with no fixed structure or representation, in contrast with some of the other evolutionary paradigm. Its main variation operator is the mutation.

Iteratively Reweighted Least Squares (IRLS): Numerical algorithm for minimizing any specified objective function using a standard weighted least squares method such as Gaussian elimination. It is widely applied in Logistic Regression.

Logistic Regression: Statistical regression model for Bernoulli-distributed dependent variables. It is a generalized linear model that uses the logit as its link function. Logistic regression applies maximum likelihood estimation after transforming the dependent into a logit variable (the natural log of the odds of the dependent occurring or not).

Precision Farming: Use of new technologies, such as global positioning (GPS), sensors, satellites or aerial images, and information management tools (GIS) to assess and understand in-field variability in agriculture. Collected information may be used to more precisely evaluate optimum sowing density, estimate fertilizers and other inputs needs, and to more accurately predict crop yields.

Product Unit Neural Networks: Alternative to standard sigmoidal neural networks, based on multiplicative nodes instead of additive ones. Concretely, the output of each hidden node is the product of all its inputs raised to a real exponent.

Remote Sensing: Short or large-scale acquisition of information of an object or phenomenon, by the use of either recording or real-time sensing devices that is not in physical or intimate contact with the object (such as by way of aircraft, spacecraft, satellite, or ship).

Multi-Objective Evolutionary Algorithms

INTRODUCTION

Real world optimization problems are often too complex to be solved through analytical means. Evolutionary algorithms, a class of algorithms that borrow paradigms from nature, are particularly well suited to address such problems. These algorithms are stochastic methods of optimization that have become immensely popular recently, because they are derivative-free methods, are not as prone to getting trapped in local minima (as they are population based), and are shown to work well for many complex optimization problems.

Although evolutionary algorithms have conventionally focussed on optimizing single objective functions, most practical problems in engineering are inherently multi-objective in nature. Multi-objective evolutionary optimization is a relatively new, and rapidly expanding area of research in evolutionary computation that looks at ways to address these problems.

In this chapter, we provide an overview of some of the most significant issues in multi-objective optimization (Deb, 2001).

BACKGROUND

Arguably, Genetic Algorithms (GAs) are one of the most common evolutionary optimization approaches. These algorithms maintain a population of candidate solutions in each generation, called chromosomes. Each chromosome corresponds to a point in the algorithm's search space. GAs use three Darwinian operators – selection, mutation, and crossover to perform their search (Mitchell, 1998). Each generation is improved by systematically removing the poorer solutions while retaining the better ones, based on a fitness measure. This process is called selection. Binary tournament selection and roulette wheel selection are two popular methods of selection. In binary tournament selection,

two solutions, called parents, are picked randomly from the population, with replacement, and their fitness compared, while in roulette wheel selection, the probability of a solution to be picked, is made to be directly proportional to its fitness.

Following selection, the crossover operator is applied. Usually, two parent solutions from the current generation are picked randomly for producing offspring to populate the next generation of solutions. The offspring are created from the parent solutions in such a manner that they bear characteristics from both. The offspring chromosomes are probabilistically subject to another operator called mutation, which is the addition of small random perturbations. Only a few solutions undergo mutation. Evolutionary Strategies (ES) forms another class of evolutionary algorithms that is closely related to GAs and uses similar operators as well.

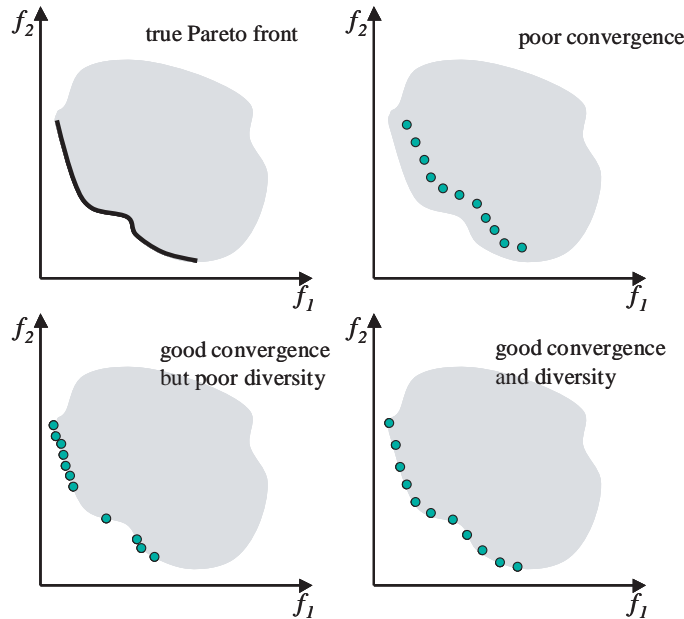

Particle Swarm Optimization (PSO) is a more recent approach (Clerc, 2005). It is modeled after the social behavior of organisms such as a flock of birds or a school of fish, and thus only loosely classified as an evolutionary approach. Each solution within the population in PSO, called a particle, has a unique position in the search space. In each generation, the position of each particle is updated by the addition of the particle's own velocity to it. The velocity of a particle, a vector, is then incremented towards best location encountered in the particle's own history (called the individual best), as well as the best position in the current iteration (called the global best).

EVOLUTIONARY ALGORITHMS FOR MULTI-OBJECTIVE OPTIMIZATION

Multi-Objective Optimization

When dealing with optimization problems with multiple objectives, the conventional theories of optimality can-

Figure 1. An illustration of convergence and diversity concepts in multi-objective optimization algorithms. The objective functions f_1 and f_2 are to be minimized.

not be applied. Instead, the concepts of dominance and Pareto-optimality are used. Without a loss of generality, we will assume that the optimization problem involves the simultaneous minimization of several objectives only. If these objective functions are $f_i(\cdot)$, $i = 1, \dots, M$, a solution x is said to *dominate* another solution y if and only if for all i , $f_i(x) \leq f_i(y)$ with at least one of the inequalities being strict. In other words, x dominates y if and only if x is as good as y for all objectives and better in at least one. This relationship is written $x \succ y$. In the set of all feasible solutions, that subset whose members are not dominated by any other in the set, is called the *Pareto set*. In other words, if \mathbf{S} is the search space, the Pareto set \mathbf{P} is given by, $\mathbf{P} = \{x \in \mathbf{S} \mid \forall y \in \mathbf{S}, y \succ x \text{ is false}\}$. The image of the Pareto set \mathbf{P} in the M dimensional objective function space is called the *Pareto front*, \mathbf{F} . Thus, $\mathbf{F} = \{(f_1(x), f_2(x), \dots, f_M(x)) \mid x \in \mathbf{P}\}$.

The goal of a multi-objective optimization algorithm is twofold. Firstly, its output, the set of non-dominated solutions in the population, must be as close to the true Pareto front as possible. This feature is called *convergence*. Secondly, in addition to good convergence, the multi-objective evolutionary algorithm should also yield solutions that sample the front at approximately

regularly spaced intervals, a feature that is usually referred to as *diversity*. Outputs, where the solutions are clustered in a few regions of the front while other regions are either omitted or poorly sampled, are not desirable. Figure 1 illustrates the concepts of good convergence and diversity.

In order to handle multi-objective optimization tasks, an evolutionary algorithm must be equipped to discriminate between solutions using either convergence or diversity as the criterion for comparison. When using convergence, the majority of current evolutionary algorithms make use of one of two basic ranking schemes that were originally put forth by Goldberg (Goldberg, 1989). The first is a method that shall be referred to here as *domination counting*. Within a population of solutions, the rank of any solution is the number of other solutions in the population that dominate it. Clearly, the non-dominated solutions in the population are assigned counts of zero. The second approach will be called *non-dominated sorting*. Here, ranks are assigned to each solution in a population, in such a manner that solutions that have the same rank do not dominate one another, each solution is assigned a lower rank than another that it dominates, and, in turn, is ranked higher

than ones dominating it. As before, non-dominated solutions in the population are assigned a rank of zero. Both concepts are illustrated in figure 2. The numbers corresponding to each solution in figure 2 (left) are the domination counts. The figure shows specifically the solution with a count of 3 being dominated by three others (with ranks 0, 0 and 2). In figure 2 (right), the solutions with equal rank (the ranks being 0, 1 or 2) are grouped together. Solutions with a rank of 0 are non-dominated ones. They dominate those with ranks 1 or 2. When they are removed, those with ranks of 1 are no longer dominated. Removing rank 1 solutions makes the rank 2 solution non-dominated.

Multi-objective evolutionary algorithms must also be equipped with the ability to discern between solutions that are in sparser regions of the M dimensional space of objective functions, from those in denser ones. The three main approaches used to do so are illustrated in figure 3. The first of these methods is to consider a *bounding hypercube* around each solution in the objective function space that does not enclose any other solution (Deb, Pratap, Agarwal & Meyarivan, 2002). Neighboring solutions will be located at some of the corners of this hypercube. This is shown in figure 3 (left), where two solutions, a and b , have been enclosed by hypercubes. The perimeters of the hypercubes are considered as measures of diversity. Solutions whose bounding hypercubes have a larger perimeter are considered to be located in sparser regions than those with smaller ones. The second approach (Knowles & Corne, 2000) is to superimpose an M -dimensional *hypergrid* in the objective function space, and consider the number of solutions that stay in each of the hypergrid's cells as a measure of how dense the region around the cell is. In figure 3 (middle), since b occupies the same cell as another solution, whereas a does not, the latter is

regarded as being placed in a sparser region. The last approach computes the k^{th} nearest neighbor of each solution (Zitzler, Laumanns & Thiele, 2001). This situation is depicted in figure 3 (right), where the solutions a and b have been connected to their nearest neighbors ($k=1$). Solutions, which lie at greater distances from their neighbors, are considered to be in sparser regions of the objective function space.

Since elitism, the guaranteed survival of the fittest solutions per generation, shows faster convergence in single objective evolutionary algorithms, this feature has also been incorporated into most current multi-objective evolutionary algorithms. Elitism is ensured by means of an archive that stores the best solutions in each generation. Quite often, the archived solutions are reinserted back into the main population. Archiving is implemented via schemes that we will refer to, collectively, as *elite preservation*.

A Few Recent Evolutionary Algorithms

(i) **NSGA-II** (Deb, Pratap, Agarwal & Meyarivan, 2002): NSGA-II (Non-dominated Sorting Genetic Algorithm) maintains a population and a separate archive, each of size N . In each generation, the population is merged with the archive. This merged set is then subject to elite preservation. The new archive is filled by taking the N best-ranked solutions obtained from elite preservation. The same N individuals are also subject to tournament selection, crossover, and mutation to form the population for the next generation.

Elite preservation is implemented in NSGA-II by using non-dominated sorting for convergence, and the hypercube method for diversity. It proposes an $O(MN^2)$ subroutine for fast non-dominated sorting to assign ranks to the solutions in the merged population.

Figure 2. Discriminating between solutions based on convergence

Figure 3. Discriminating between solutions based on diversity

Starting with the lowest ranked solutions, the archive is filled until it reaches its full capacity N .

Diversity is invoked to further discriminate between mutually non-dominating solutions when not all solutions of an identical rank can be inserted into the archive. NSGA-II incorporates an algorithm of order $O(MN \log(N))$ to do so. Because non-dominated sorting is the computationally rate limiting portion in NSGA-II, the overall complexity is $O(MN^2)$ per generation.

(ii) **SPEA-2** (Zitzler, Laumanns & Thiele, 2001): The SPEA-2 (Strength Pareto Evolutionary Approach) method is quite similar to NSGA-II. It also maintains a population and an archive of size N , merging both in the beginning of every generation and making use of elite preservation to identify the best to undergo crossover and mutation for the next generation. In SPEA-2, individual fitness are computed in a two-step manner, that is an improved version of the basic domination counting approach discussed earlier. First to be computed is the strength of each solution in the merged population, *i.e.*, the number of solutions it dominates. Then, the raw fitness of each individual is computed as the sum of the strengths of all the solutions that dominate it.

In (Zitzler, Laumanns & Thiele, 2001) it is argued that this method of computing fitness imparts SPEA-2 with some capability to preserve diversity. However, in itself, raw fitness is inadequate to do so, and so a separate term is added to it, that explicitly takes diversity into account. This second term added to each solution's fitness, is inversely related to the distance from the solution to its k^{th} nearest neighbor in objective function space. The overall algorithm complexity of SPEA-2 is $O(MN^3)$ per generation.

(iii) **MOPSO** (Coello Coello, 2004): MOPSO (Multi-objective Particle Swarm Optimization) is an

approach for fast multi-objective optimization that is based on PSO. It imposes population diversity by means of the M -dimensional hypergrid described earlier, and counting the number of solutions present in each of the hypergrid's cells. Solutions occupying cells with lower counts are preferred to those with higher counts. An even distribution of solutions along the Pareto front is achieved by biasing particles to update their velocities towards global best particles that are located in sparser cells of the hypergrid, *i.e.* with lower counts. This is done using a roulette wheel selection algorithm that picks a cell probabilistically using cell counts, such that the higher the cell count, the lower the probability of selection becomes. MOPSO also implements a mutation operator.

(iv) **ParEGO** (Knowles, 2006): ParEGO (Parallel Efficient Global Optimization) has been explicitly designed for problems where evaluating the objective function is highly expensive in terms of computer time. Therefore, ParEGO converges in as few function evaluations as possible. The algorithm uses a Gaussian process model to approximate the fitness landscape that is learned adaptively using supervised learning. For further details one is referred to (Knowles, 2006).

(v) **FSGA** (Koduru, Das, Welch & Roe, 2004): FSGA (Fuzzy Simplex Genetic Algorithm) has a complexity of $O(MN^2)$ per generation similar to NSGA-II. It differs from NSGA-II and SPEA-2 in the method used for elite preservation. A measure called fuzzy dominance is used for the purpose. A solution that is not dominated by any other is assigned a fuzzy dominance of zero. The poorer a solution is, the higher the fuzzy dominance value it is assigned. FSGA's fuzzy dominance is a numerical method that not only uses Pareto-optimality, but also considers the degree to which one solution dominates

another, making effective use of differences between their values of the objective functions. It has been designed specifically so that FSGA can be hybridized readily with a local search algorithm.

PAES (The Pareto Archive Evolutionary Strategy) and PESA (Pareto Envelope based Selection Algorithm) are other successful multi-objective evolutionary algorithms that make use of the hypergrid to measure diversity (Knowles & Corne, 2000, Corne, Jerram, Knowles & Oates, 2001). Another algorithm, RDGA (Rank Density based Genetic Algorithm) uses this method along with a ranking scheme wherein a non-dominated individual has unit rank and others are assigned one plus the sum of the ranks of all solutions that dominate them (Lu & Yen, 2003). Very recently, the use of fuzzy dominance has been successfully applied to another multi-objective PSO algorithm (Koduru, Das & Welch, 2007).

FUTURE TRENDS

Multi-objective evolutionary optimization is a rapidly expanding, new field of research. Although several interesting approaches have been proposed in the recent literature, further investigation is necessary before multi-objective algorithms can truly address the needs of the application domains.

One current research focus is in devising numerical metrics to compare solutions. This is particularly useful when the problem contains a large number of objectives. In higher dimensional objective function space, it is less likely to find a solution that dominates another, i.e. is better than or equal to another in all objectives. Under these circumstances, comparing solutions that are already within the Pareto front is essential. One such method has been suggested recently (Farina & Amato, 2004). This method counts the number of objectives along which one solution is better than and worse than another, and proposed fuzzy metrics based on the counts. However, such ideas have yet to be incorporated within evolutionary algorithms. A related direction of research is in devising schemes to compare solutions in the presence of uncertainty in objective functions. This research has obvious practical implications in engineering and other applications where measuring objectives such as cost, efficiency or expected lifetime are difficult tasks (Fieldsend, Everson & Singh, 2005).

Another direction of certain future interest is in multi-objective optimization using novel biological paradigms. Only a few multi-objective PSO algorithms, such as MOPSO, and fuzzy dominance based PSO method (Koduru, Das & Welch, 2007), have been proposed; consequently, there is great interest in devising better PSO search strategies within the evolutionary computation community. Another class of algorithms based on computations involved in the vertebrate immune system is emerging, called Artificial Immune Systems (AIS). Although a few multi-objective AIS algorithms have been proposed recently (*cf.* Coello Coello & Cortés, 2005), there is substantial scope for improvement in this direction.

Other trends are in devising more difficult benchmark test problems. Huband *et al.* have proposed recent benchmarks (Huband, Hingston, Barone & While, 2006), and the performance of evolutionary methods for these functions need to be investigated.

CONCLUSION

We have provided an overview of the new and expanding field of multi-objective optimization, outlining some of the most significant approaches. We chose to describe NSGA-II and SPEA-2 as they are the most popular algorithms today. We also discuss the recent algorithm, ParEGO, which is very promising for some specialized applications as well as the even more recent FSGA, currently under development, which fills the need for hybrid multi-objective algorithms. Finally, we also have outlined MOPSO, which is based on a new evolutionary paradigm, PSO. Lastly, we address future trends in evolutionary multi-objective optimization to complete the discussion.

KEY TERMS

Elitism: A strategy in evolutionary algorithms where the best one or more solutions, called the elites, in each generation, are inserted into the next, without undergoing any change. This strategy usually speeds up the convergence of the algorithm. In a multi-objective framework, any non-dominated solution can be considered to be an elite.

Evolutionary Algorithm: A class of probabilistic algorithms that are based upon biological metaphors such as Darwinian evolution, and widely used in optimization.

Fitness: A measure that is used to determine the goodness of a solution for an optimization problem.

Fitness Landscape: A representation of the search space of an optimization problem that brings out the differences in the fitness of the solutions, such that those with good fitness are “higher”. Optimal solutions are the maxima of the fitness landscape.

Generation: A term used in evolutionary algorithms that roughly corresponds to each iteration of the outermost loop. The offspring obtained in one generation become the parents of the next.

Multi-Objective Optimization: An optimization problem involving more than a single objective function.

In such a setting, it is not easy to discriminate between good and bad solutions, as a solution, which is better than another in one objective, may be poorer in another. Without any loss of generality, any optimization problem can be cast as one involving minimizations only.

Objective Function: The function that is to be optimized. In a minimization problem, the fitness varies inversely as the objective function.

Population Based Algorithm: An algorithm that maintains an entire set of candidate solutions, each solution corresponding to a unique point in the search space of the problem.

Search Space: Set of all possible solutions for any given optimization problem. Almost always, a neighborhood around each solution can also be defined in the search space.

INTRODUCTION

Traditionally, the application of a neural network (Haykin, 1999) to solve a problem has required to follow some steps before to obtain the desired network. Some of these steps are the data preprocessing, model selection, topology optimization and then the training. It is usual to spend a large amount of computational time and human interaction to perform each task of before and, particularly, in the topology optimization and network training. There have been many proposals to reduce the effort necessary to do these tasks and to provide the experts with a robust methodology. For example, Giles et al. (1995) provides a constructive method to optimize iteratively the topology of a recurrent network. Other methods attempt to reduce the complexity of the network structure by mean of removing unnecessary network nodes and connections like in (Morse, 1994). In the last years, evolutionary algorithms have been shown as promising tools to solve this problem, existing many competitive approaches in the literature. For example, Blanco et al. (2001) proposed a master-slave genetic algorithm to train (master algorithm) and to optimize the size of the network (slave algorithm). For a general view of the problem and the use of evolutionary algorithms for neural network training and optimization, we refer the reader to (Yao, 1999).

Although the literature about genetic algorithms and neural networks is very extensive, we would like to remark the recent popularity of multi-objective optimization (Coello et al., 2002, Jin, 2006), specially to solve the problem of simultaneous training and topology optimization of neural networks. These methods have shown to perform suitably for this task in previous works, although most of them are proposed for feedforward models. They attempt to optimize the

structure of the network (number of connections, hidden units or layers), while training the network at the same time. Multi-objective algorithms may provide important advantages in the simultaneous training and optimization of neural networks: They may force the search to return a set of optimal networks instead of a single one; they are capable to speed-up the optimization process; they may be preferred to a weight-aggregation procedure to cover the regularization problem in neural networks; and they are more suitable when the designer would like to combine different error measures for the training. A recent review of these techniques may be found in (Jin, 2006).

BACKGROUND

Multi-objective algorithms have become popular in the last years to solve the problem of the simultaneous training and topology optimization of neural networks, because of the innovations they can provide to solve it. Certain authors have addressed this problem through the evolution of single ensembles as for example with DIVACE-II (Chandra et al., 2006), which also implements different levels of coevolution. In other works, the networks are fully evolved and the evolutionary operators are designed to deal with both training and structure optimization. Some authors have addressed the problem of the structure optimization attending to reduce either the number of network neurons or either the number of network connections. In the first methods (Abbass et al., 2001; Delgado et al., 2005; González et al., 2003), the optimization is easier since the codification of a network contains a smaller number of freedom degrees than the last methods; however, they have a disadvantage in the sense that the networks obtained are fully connected. On the other hand, the methods in

the second place (Jin et al., 2004; Cuéllar et al, 2007) attempt to reduce the number of connections but it is not ensured that also the number of network nodes is also minimum. Nevertheless, experimental results have shown that the networks obtained with these proposals have a low size (Jin et al, 2004).

The hybridation of multi-objective evolutionary algorithms with traditional gradient-based training algorithms has also provided promising results. While the evolutionary algorithm makes a wide exploration of the solution space, the gradient-based algorithms are capable to address the search to promising areas during the evolution and to exploit the solutions suitably. This hybridation is usually carried out by including the gradient-based training method as a local search operator in the evolutionary process. Then, the local search operator is applied after the mutation and before the evaluation of the solutions. Some examples are the system MPANN developed by H.A. Abbass (2001), and the works by Y. Jin et al. (2006).

In the next section, we make an study of different aspects concerning the multi-objective optimization of neural networks. Concretely, we make an study of the objectives to be achieved in the multi-objective algorithm and the multi-objective algorithms used. We focus our analysis on recurrent neural networks (Haykin, 1999; Mandic and Chambers, 2001), since these models have a high complexity due to the recurrence. The experiments are illustrated in problems of time-series prediction, since this type of problems has multiple applications in many research and enterprise areas and the neural models used are suitable for this application, as suggested by previous works (Aussem, 1999).

MULTI-OBJECTIVE EVOLUTIONARY ALGORITHMS FOR NEURAL NETWORKS TRAINING AND OPTIMIZATION

The most recent multi-objective evolutionary algorithms are based in the concept of Pareto dominance as a criterion to determine whether a solution is optimal or not. Let $F(s) = (f_1(s), f_2(s), \dots, f_k(s))$ be a set of k objectives to be achieved, and let s_1 and s_2 be two solutions. In a minimization problem, it is said that s_2 is dominated by s_1 if, and only if:

$$(f_i(s_1) \leq f_i(s_2), \forall i : 1 \leq i \leq k) \wedge (\exists j : f_j(s_1) < f_j(s_2) : 1 \leq j \leq k) \quad (1)$$

The solutions that are non-nominated by any other solution are called the *non-dominated set* or *Pareto frontier*. The goal of any multi-objective algorithm is to find the solutions in the Pareto frontier. Thus, the selection of the objectives to be achieved in a multi-objective algorithm is a key aspect, since they will be used to guide the search across the search space to obtain the optimal solutions. However, the higher the number of objectives is, the higher the complexity of the search space is. In this work, we attempt to train and optimize the size of an Elman Network (Mandic and Chambers, 2001), for time series prediction problems. This network type has an input layer, an output layer and a hidden layer. The data of the time series is provided in time to the network inputs, and the objective is the network output to provide the future values of the time series at the output. The recurrent connections are in the hidden layer, so that the output of a hidden neuron at time t is also input for all the hidden neurons at time $t+1$. The reader may found a wider information about dynamical recurrent neural networks applied for time series prediction in (Aussem, 1999; Mandic and Chambers, 2001).

$$f_1(s^*) = \min \{ f_1(s) \} = \min \left\{ \frac{1}{T} \sum_{t=1}^T (Y(t) - O(t))^2 \right\} \quad (2)$$

$$f_2(s^*) = \min \{ f_2(s) \} = \min \{ h(s) \} \quad (3)$$

$$f_3(s^*) = \min \{ f_3(s) \} = \min \{ n(s) \} \quad (4)$$

For the problem of neural network optimization and training, we consider three objectives to be achieved (see equations (2)-(4)). The objective $f_1(s)$ attempts to minimize the network error, while $f_2(s)$ is used to optimize the number of hidden neurons and $f_3(s)$ the number of network connections. In equation (2), T is the number of training patterns, $Y(t)$ is the desired output for pattern t and $O(t)$ is the network output. In equation (3), $h(s)$ is the number of hidden neurons for the network s ; and $n(s)$ is the number of network connections in equation (4). Another issue related to the objectives is the network codification. For example, in

works like in (Abbass, 2001), the objectives to achieve are $(f_1(s), f_2(s))$, obtaining fully connected networks. In this cases, the representation of the network attempts to codify the neurons if a binary vector, and the network weights in a matrix with real values. In other works like in (Jin et al., 2006), the network connections are codified into a binary matrix and the network weight into a matrix with real values, since the objectives to be optimized are $(f_1(s), f_3(s))$. If we would consider to optimize all the objectives, the representation should contain the network structure (hidden neurons and connections) and the weights. In our proposal, the number of network neurons are codified with an integer value following the guidelines in (Delgado et al., 2005; Cuéllar et al., 2007), the connections are codified in a binary vector, and the network weights in a vector with real

values. Figure 1 shows an example of the codification of an Elman network into a solution, where V_{ij} are the network weights from input j to hidden neuron i , U_{ir} is the recurrent weight from neuron r to neuron i and W_{oi} are the weights from hidden neuron i to the output neuron o . A network connection is active if the corresponding gene is set to 1. Otherwise, the connection is not active.

The evolutionary operators like the crossover and the mutation should consider two different areas in a solution: Structural recombination/mutation, and genetic recombination/mutation. The genetic one is associated to the area of the network weights, while the structural one is for the network topology. Additionally, it could be included a local search operator to improve the network performance locally in the area that codifies the network weights, as suggested in the previous section. In our experiments, we have used a simple recombination that generates two children from two parents, with no structural recombination: We have tested that the structural recombination could provide a high exploitation of the solution space, and the selective pressure produced by the objectives to be achieved could then produce a premature convergence. On the other hand, for the mutation we have included three probabilities since the structural mutation may have a high impact in the population of solutions: Structural mutation is selected with probability p_1 , and genetic mutation with probability $1 - p_1$. In the structural mutation, the number of hidden neurons is altered with probability p_2 ; otherwise, the active/inactive connections are mutated. Finally, a gene is altered with probability p_3 . Figure 2 shows an example of the crossover, and Figure 3 shows an example of the structural mutation for the number of

Figure 1. Example for the codification of an Elman network with 1 input, 1 output, 2 hidden neurons and 5 connections

Figure 2. Example of the crossover

Figure 3. Example of mutation

hidden neurons. In this last case, the solution grows to have three hidden neurons, and new genes are generated. The values for these genes are a random number in the bounds of the gene. In Figure 3, these genes may be recognized by mean of the symbol ?.

For the experiments, we attempt to study the benefits of the inclusion of a higher number of objectives to achieve in the multi-objective algorithm, and the effects of the evolutionary algorithm. To illustrate our results, we have selected two social-economic time-series for forecasting: The evolution of the U.S. population from 1950 to 2004 taken monthly (*USPop*), and the evolution of the euro/U.S. dollar variation from 1995 to 2004, taken monthly (*EurDol*). The 80% of the data are used for training, and the remaining 20% is for the test. Both time series may be downloaded for free

from <http://www.economag.com>. The parameter for the networks in our experiments are bounded for the number of hidden neurons, from 3 to 12. The networks have one input for the value of the time series at time t , and one output for the value of the time series at time $t+1$, to be predicted. There have been 30 experiments with the multiobjective algorithms, which are based in the algorithms *NSGA2* (Deb et al, 2002) and *SPEA2* (Zitzler et al, 2001). We label *NSGA2* and *SPEA2* for the algorithms that optimize the objectives $(f_1(s), f_2(s))$ and *NSGA2.connect* and *SPEA2.connect* for the algorithms that optimize $(f_1(s), f_2(s), f_3(s))$. The stopping criterion is to have 10000 solutions evaluated, and size of the population is 50. The parameters for mutation are $(p_1, p_2, p_3)=(0.5, 0.5, 0.1)$ and the range for the genes containing network weights is $[-5.0, 5.0]$. We have used the binary tournament selection, the heuristic Wright's crossover and the displacement mutation for the evolutionary operators.

Figure 4 draws the distribution of the performance for the neural networks obtained in the Pareto frontiers for the 30 experiments, in each data set. Additionally, Table 1 shows the best Pareto frontiers obtained, where Column 1 plots the algorithm, columns 2 and 5 expose the number of hidden neurons, columns 3 and 6 describe the number of network connections, and columns 4 and 7 the Mean Square Error (MSE) in the training.

We may observe that *SPEA2.connect* has obtained a Pareto frontier wider than *NSGA2.connect* in both problems. In some situations, this fact may be desir-

Figure 4. Boxplots for the distribution of network performance in *USPop* (a), and *EurDol* (b)

Table 1. Best Pareto frontiers obtained in the data sets

| Algorithm | USPop | | | EurDol | | |
|---------------|--------------|-------------|-------|--------------|-------------|-------|
| | Hidden units | Connections | MSE | Hidden units | Connections | MSE |
| SPEA2.connect | 3 | 6 | 0.042 | 3 | 11 | 0.013 |
| | 5 | 17 | 0.041 | 4 | 7 | 0.012 |
| | 11 | 43 | 0.028 | 5 | 16 | 0.009 |
| | 10 | 44 | 0.050 | | | |
| SPEA2 | 4 | 24 | 0.021 | 4 | 24 | 0.016 |
| NSGA2.connect | 3 | 10 | 0.092 | 3 | 4 | 0.013 |
| | | | | 5 | 17 | 0.012 |
| NSGA2 | 7 | 63 | 0.007 | 4 | 24 | 0.003 |

able, since we are provided with a larger set of optimal networks from we could select the best appropriate network to solve our problem. On the other hand, figures 4.a and 4.b suggest that the inclusion of the network connections optimization in the multi-objective method may produce poorer results. In both problems, the best solutions are provided by the algorithm *NSGA2*, which return fully connected networks. The same algorithm that also optimize the number of connections, *NSGA2.connect*, provides networks with minimum size, but the network performance are lower. In the case of the algorithms based on *SPEA2*, we may notice that *SPEA2.connect* is the less robust algorithm, since the distribution in the MSE is the widest. However, the boxplot shows that the best solutions of this method may be similar to the ones from *NSGA2*. This fact suggests that we may encounter smaller networks using the three objectives in *SPEA2.connect*, but sacrificing some improvements in the network performance and spending more computational time to obtain a suitable solution. Moreover, the networks obtained with the inclusion of objective $f_3(s)$ in the optimization process have a size which is very low being compared with the fully connected networks from *SPEA2* and *NSGA2*.

FUTURE TRENDS

We have studied in the previous section that the inclusion of a larger number of objectives for the network optimization is able to reduce the size of the network, although the network performance obtained is poorer. This is usual since the more objectives to be optimized, the more complex is the search space and

therefore to find optimal solutions. The hybridation of multi-objective evolutionary algorithms with non-linear programming methods to address the search space to promising areas have proved to work well in the works that propose a lower number of objectives in the optimization. In the case studied in this work, the improvements of these procedures could be better since the size of the search space is wider. Another important issue is the research of the evolution considering diversity and convergence: The objectives used usually introduce a high selective pressure in the population, and specially the objectives for the topology optimization. This could be addressed by introducing components in the evolutionary process to control the balance in diversity/convergence, therefore improving the search process and the exploration/exploitation of the solution space.

Another interesting line to work is the inclusion of objectives to improve another properties of neural networks like noise tolerance or generalization. For example, this issue has been suggested in (Graning et al, 2006), where it is introduced an extra objective to improve the generalization of a feedforward network in binary classification.

CONCLUSION

In this work, we have studied the benefits and disadvantages in multi-objective training and fully topology optimization of recurrent neural networks. We have tested the methods in time series prediction problems, and they have been also compared with the methods that do also optimize the number of connections. In general

terms, all the algorithms have solved the problems suitably. The methods studied provide networks with minimum number of hidden units and connections, and the network performance is

good. However, these methods may produce poorer results than those that only optimize the number of hidden neurons and provide fully connected networks. Using a higher computational time, the results from the algorithms that optimize the topology, in terms of hidden neurons and connections, may be competitive, providing networks with performance similar to those techniques that do not optimize the number of network connections. Moreover, these methods include the advantage that the network's size is very low, being compared with the fully connected networks.

KEY TERMS

Dynamical Recurrent Neural Networks: Artificial neural network that include recurrent connections in the network structure. They are capable to process patterns with undetermined size and/or indexed in time. The output in these networks at time $t+1$ are computed using the network inputs at time t and the network state, provided by the recurrent connections.

Ensembles: Self-containing area of a neural network (neuron, connection, set of a neuron with connections...) that, being combined with other ensembles, is able to build a neural network that solves a problem.

Evolutionary Algorithm: Optimization algorithm based on Darwinian nature evolution.

Multi-Objective Optimization: Optimization of a problem that involves the satisfiability or optimization of two or more objectives, sometimes opposed each other.

Regularization: Optimization of both complexity and performance of a neural network following a linear aggregation or a multi-objective algorithm.

Time-Series: Data sequence indexed in time.

Time-Series Prediction: Problem that involves the prediction of the future values of a time series, considering a few values from the data set in the past.

“Narrative” Information and the NKRL Solution

N

Gian Piero Zarri

LaLIC, University Paris 4-Sorbonne, France

INTRODUCTION

In a companion article of this Encyclopaedia: ‘Narrative’ Information, the Problem, we have introduced the problem of finding a complete and computationally efficient system for representing and managing ‘*nonfictional narrative information*’. We have stressed there the *important economic value of this multimedia type of information* – that concerns, e.g., corporate memory documents, news stories, normative and legal texts, medical records, intelligence messages, surveillance videos or visitor logs, actuality photos, eLearning and Cultural Heritage material, etc. We have also emphasised that the usual Computer Science tools – including those pertaining to the now very popular ‘Semantic Web’ domain, see (Bechhofer *et al.*, 2004, Beckett, 2004) – *are not really suitable* for dealing with this type of information.

BACKGROUND

In this article, we will present an Artificial Intelligence tool, NKRL (Narrative Knowledge Representation Language) that has been especially developed for dealing in an ‘intelligent’ way with the nonfictional narrative information. NKRL is, at the same time:

- a *knowledge representation system* for describing in the best possible detail the essential content (the ‘meaning’) of complex nonfictional ‘narratives’;
- a *system of reasoning (inference) procedures* that, thanks to the richness of the representation system, is able to automatically establish ‘interesting’ relationships among the represented data;
- an *implemented software environment* that allows the user to encode the original narratives in terms of the representation language to create ‘NKRL knowledge bases’ in a specific application domain and to exploit ‘intelligently’ these bases.

The main innovation introduced by NKRL with respect to the usual ontological paradigms concerns the addition to the traditional *ontology of concepts* – called HClass, ‘hierarchy of classes’ in the NKRL’s jargon – an *ontology of events*, i.e., a new sort of hierarchical organization where the nodes correspond to *n*-ary structures called ‘*templates*’ (HTemp, ‘hierarchy of templates’). A partial image of the ‘upper level’ of HClass – that follows then the standard Protégé approach, see (Noy *et al.*, 2000) – is given in Figure 1; for HTemp, see Table 1 and Figure 2 below.

A SHORT DESCRIPTION OF NKRL

Instead of using the traditional (binary) *attribute/value* organization, the templates are generated from the

Figure 1. A partial representation of the ‘upper level’ of HClass, the NKRL ‘traditional’ ontology of concepts.

n -ary combination of quadruples connecting together the *symbolic name* of the template, a *predicate*, and the *arguments* of the predicate introduced by named relations, the *roles*. The quadruples have in common the *name* and *predicate* components. Denoting then with L_i the generic symbolic label identifying a given template, with P_j the predicate used in the template, with R_k the generic role and with a_k the corresponding argument, the core data structure for templates has the following general format (see also the companion article, ‘Narrative’ Information, the Problem):

$$(L_i (P_j (R_1 a_1) (R_2 a_2) \dots (R_n a_n))) \quad (1)$$

Predicates pertain to the set {BEHAVE, EXIST, EXPERIENCE, MOVE, OWN, PRODUCE, RECEIVE}, and roles to the set {SUBJ(ect), OBJ(ect), SOURCE, BEN(e)F(iciary), MODAL(ity), TOPIC, CONTEXT}. An argument of the predicate can consist of a simple ‘concept’ or of a structured association (‘expansion’) of several concepts. Templates can be conceived as the *formal representation of generic classes of elementary events* like “move a physical object”, “be present in a place”, “produce a service”, “send/receive a message”, etc. When a particular event pertaining to one of these general classes must be represented, the corresponding template is *instantiated* to produce a *predicative occurrence*.

To represent then a simple narrative like: “On November 20, 1999, in an unspecified village, an armed group of people has kidnapped Robustiniano Hablo”, we must then select firstly in the HTemp hierarchy the template corresponding to “execution of violent actions”, see Figure 2 and Table 1 below – this example refers to a recent application of NKRL in a ‘terrorism’ context in the framework of an European project see, e.g., (Zarri, 2005).

As it appears from Table 1a, the arguments of the predicate (the a_k terms in (1)) are represented by *variables with associated constraints* expressed as HClass concepts or combinations of concepts. When deriving a predicative occurrence (an instance of a template) like mod3.c5 in Table 1b, the role fillers in this occurrence must conform to the constraints of the father-template. For example, ROBUSTINIANO_HABLO (the ‘BEN(e)F(iciary)’ of the action of kidnapping) and INDIVIDUAL_PERSON_20 (the unknown ‘SUBJECT’, actor, initiator etc. of this action) are both ‘individuals’, instances of the HClass concept individual_person. The

constituents – as SOURCE in Table 1a – included in square brackets are optional. A ‘conceptual label’ like mod3.c5 is the symbolic name used to identify the NKRL code corresponding to a specific predicative occurrence.

The ‘attributive operator’, SPECIF(ication), is one of the four operators used in NKRL for the construction of ‘structured arguments’ (‘complex fillers’ or ‘expansions’) see, e.g., (Zarri, 2003). The SPECIF lists, with syntax (SPECIF $e_i p_1 \dots p_n$), are used to represent the properties or attributes that can be asserted about the first element e_i , concept or individual, of the list – e.g., in the SUBJ filler of mod3.c5, Table 1b, the attributes weapon_wearing and (SPECIF cardinality_several_) are both associated with INDIVIDUAL_PERSON_20.

The ‘location attributes’, represented in the predicative occurrences as lists, are linked with the arguments of the predicate by using the colon operator, ‘:’, see the individual VILLAGE_1 in Table 1b. In the occurrences, the two operators date-1, date-2 materialize the temporal interval normally associated with narrative events, see (Zarri, 1998) – and, more in general, (Allen, 1981, Ferro *et al.*, 2005).

150 templates are permanently inserted into HTemp; Figure 2 reproduces the ‘external’ organization of the PRODUCE branch of HTemp. This branch includes the Produce:Violence template used in Table 1. HTemp corresponds then to a sort of ‘catalogue’ of narrative formal structures, that are very easy to ‘customize’ to derive the new templates that could be needed for a particular application.

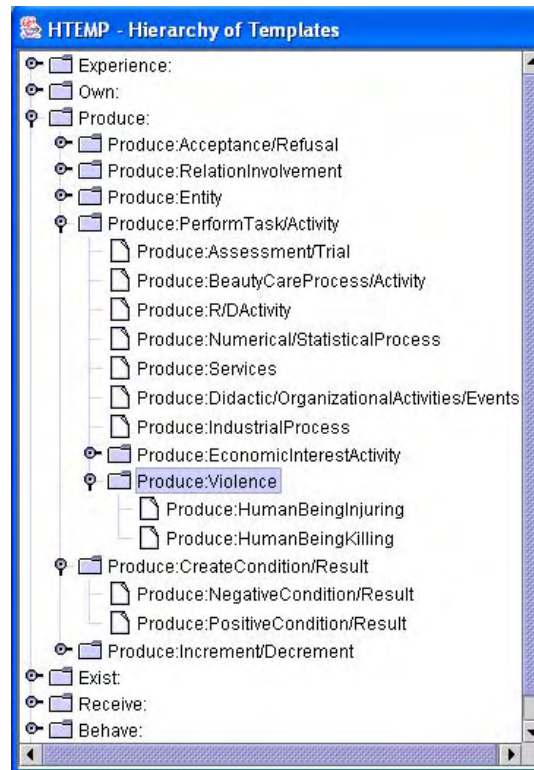

What expounded until now illustrates the NKRL solutions to the problem of representing ‘elementary’ (simple) events. To deal now with those ‘connectivity phenomena’ that arise when several elementary events are connected through causality, goal, indirect speech etc. links – see also (Mani and Pustejovsky, 2004) – the basic NKRL knowledge representation tools have been complemented by more complex mechanisms that make use of second order structures, see (Zarri, 2003). For example, the *binding occurrences* consist of lists of symbolic labels (c_i) of predicative occurrences; the lists are differentiated using specific binding operators like GOAL, CONDITION and CAUSE. Let us suppose that, in Table 1, we state now that: “...an armed group of people has kidnapped Robustiniano Hablo *in order to* ask his family for a ransom”, where the new elementary event: “the unknown individuals will ask for a ransom” corresponds to a new predicative occurrence, e.g., mod3.

Figure 2A. Partial representation of the *PRODUCE* branch of *HTemp*, the 'ontology of events'

c7. To represent this situation, we must add to the occurrences that represent the two elementary events a new *binding occurrence*, e.g., mod3.c8, to link together the conceptual labels mod3.c5 (corresponding to the kidnapping occurrence, see also Table 1b) and mod3.c7 (corresponding to the new occurrence describing the intended result). mod3.c8 will have then the form: "mod3.c8) (GOAL mod3.c5 mod3.c7)". The meaning of mod3.c8 can be paraphrased as: "the activity described in mod3.c5 is focalised towards (GOAL) the realization of mod3.c7".

Reasoning in NKRL ranges from the direct questioning of an NKRL knowledge base making use of *search patterns* (formal queries over the contents of the knowledge base) that try to unify the predicative occurrences of the base to *high-level inference procedures*. A simple example of search pattern is supplied in Table 1c, producing as an answer, among other things, the predicative occurrence mod3.c5 of Table 1b – see (Ellis, 1995, Corbett, 2003, etc.) for the techniques used to unify complex conceptual structures. With respect now to the high level procedures – a detailed

paper on this topic is (Zarri, 2005) – the *transformation rules* try to 'adapt', from a semantic point of view, the original query/queries (search patterns) that failed to the real contents of the existing knowledge bases. The principle employed consists in using rules to *automatically 'transform'* the original query (i.e., the original search pattern) into one or more different queries (search patterns) that are not strictly 'equivalent' but only 'semantically close' to the original one. Let us suppose that, e.g., during the search for all the possible information linked with the Robustiniano Hablo's kidnapping, we ask the system whether Robustiniano Hablo is wealthy. In the absence of a direct answer, the system will automatically 'transform' the original query using a rule like: "In a context of ransom kidnapping, the certification that a given character is wealthy or has a professional role can be substituted by the certification that: i) this character has a tight kinship link with another person, and ii) this second person is a wealthy person or a professional people". The final result can then be paraphrased in this way: we do not know whether Robustiniano Hablo is wealthy, but we

can say that his father is a wealthy businessperson, see (Zarri, 2005) for the details.

Hypothesis rules allow building up ‘reasonable’ logic/semantic connections among the data stored in an NKRL knowledge base using a number of pre-defined reasoning schemata, e.g., ‘causal’ schemata. For example, to mention a ‘classic’ NKRL example, after having directly retrieved through the use of a search pattern an information like: “Pharmacopeia, an USA biotechnology company, has received 64,000,000 dollars from the German company Schering in connection with an R&D activity”, we could be able to automatically construct a sort of ‘causal explanation’ of this event by retrieving information like: i) “Pharmacopeia and Schering have signed an agreement concerning the production by Pharmacopeia of a new compound” and ii) “in the framework of the agreement previously mentioned, Pharmacopeia has actually produced the new compound”.

In Table 2, we give the informal description of the reasoning steps (called ‘condition schemata’ in a hypothesis context) that must be validated to prove that a generic ‘kidnapping’ corresponds, in reality, to a more precise ‘kidnapping for ransom’ environment. When several reasoning steps must be *simultaneously* validated, as in Table 2, a failure is always possible. To overcome this problem – and, at the same time, discover all the possible *implicit information* associated with the original data – the two inference modes, transformation and hypotheses, can be used in an *integrated way*, see (Zarri, 2005). In practice, we make use of ‘transformations’ within a ‘hypothesis’ context. This means that, whenever a ‘search pattern’ is derived from a ‘condition schema’ of a hypothesis to implement one of the steps of the reasoning process, we can use it ‘as it is’ – i.e., as originally coded when the inference rule has been built up – but also in a ‘transformed’ form if the appropriate

transformation rules exist within the system.

Making use of the transformation rules already existing within the system, the hypothesis represented in an informal way in Table 2 becomes, in practice, *potentially equivalent* to the hypothesis of Table 3. For example, the proof that the kidnappers are part of a terrorist group or separatist organization (reasoning step Cond1 of Table 2) can be now obtained *indirectly*, transformation T3, by checking whether they are members of a specific subset of this group or organization.

FUTURE TRENDS

NKRL is a fully implemented language/environment. The software exists in two versions, an ORACLE-supported and a file-oriented one. Future improvements will concern mainly:

- The addition of features that will allow us querying the system in Natural Language. Very encouraging experimental results have already been obtained in this context thanks to the combined use of shallow parsing techniques – see, e.g., (Koster, 2004) and of the standard NKRL inference capabilities.
- On a more ambitious basis, the introduction of some features for the semi-automatic construction of the knowledge base of annotation/occurrences making use of full NL techniques. Some preliminary work in this context has been realised making use of the syntactic/semantic Cafetière tools, see (Black *et al.*, 2003, 2004).
- The introduction of optimisation techniques for the (basic) chronological backtracking of the NKRL InferenceEngine, in the style of the well-known techniques developed in a Logic Programming context see, e.g., (Clark and Tärnlund, 1982).

Table 2. Inference steps for the ‘kidnapping for ransom’ hypothesis

| | |
|---------|--|
| (Cond1) | The kidnappers are part of a separatist movement or of a terrorist organization. |
| (Cond2) | This separatist movement or terrorist organization currently practices ransom kidnapping of particular categories of people. |
| (Cond3) | In particular, executives or assimilated categories are concerned. |
| (Cond4) | It can be proved that the kidnapped is really a businessperson or assimilated. |

Even in its present form, NKRL has been able to deal successfully, in a 'intelligent information retrieval' mode, with the most different 'narrative' domains – from history of France to terrorism, from Falkland War to the corporate domain, from the legal field to the beauty care domain or the analysis of customers' motivations, etc.

CONCLUSION

In this article, we have supplied some details about NKRL (Narrative Knowledge Representation Language), a fully implemented, up-to-date knowledge representation and inference system especially created for an 'intelligent' exploitation of narrative knowledge. The main innovation of NKRL consists in associating with the traditional ontologies of concepts an

'ontology of events', i.e., a hierarchical arrangement where the nodes correspond to n -ary structures called 'templates'.

Table 3. 'Kidnapping' hypothesis in the presence of transformations concerning intermediary inference steps

- (Cond1) The kidnappers are part of a separatist movement or of a terrorist organization.
- (Rule T3, Consequent1) Try to verify whether a given separatist movement or terrorist organization is in strict control of a specific sub-group and, in this case,
 - (Rule T3, Consequent2) check if the kidnappers are members of this sub-group. We will then assimilate the kidnappers to 'members' of the movement or organization.
- (Cond2) This movement or organization practices ransom kidnapping of given categories of people.
- (Rule T2, Consequent) The family of the kidnapped has received a ransom request from the separatist movement or terrorist organization.
 - (Rule T4, Consequent1) The family of the kidnapped has received a ransom request from a group or an individual person, and
 - (Rule T4, Consequent2) this second group or individual person is part of the separatist movement or terrorist organization.
 - (Rule T5, Consequent1) Try to verify if a particular sub-group of the separatist movement or terrorist organization exists, and
 - (Rule T5, Consequent2) check whether this particular sub-group practices ransom kidnapping of particular categories of people.
 - ...
- (Cond3) In particular, executives or assimilated categories are concerned.
- (Rule T0, Consequent1) In a 'ransom kidnapping' context, we can check whether the kidnapped person has a strict kinship relationship with a second person, and
 - (Rule T0, Consequent2) (in the same context) check if this second person is a businessperson or assimilated.
- (Cond4) It can be proved that the kidnapped person is really an executive or assimilated.
- (Rule T6, Consequent) In a 'ransom kidnapping' context, 'personalities' like physicians, journalists, artists etc. can be assimilated to businesspersons.

KEY TERMS

Attributive Operator: The ‘attributive operator’, SPECIF(ication), is one of the four operators used in NKRL for the construction of ‘structured arguments’ (‘complex fillers’ or ‘expansions’) of the conceptual predicates. The SPECIF lists, with syntax (SPECIF $e_i p_1 \dots p_n$), are used to represent the properties or attributes that can be asserted about the first element e_i , concept or individual, of the list.

Binding Occurrences: Second order structures used to deal with those ‘connectivity phenomena’ that arise when several elementary events are connected through causality, goal, indirect speech etc. links. They consists of lists of symbolic labels (c_i) of predicative occurrences; the lists are differentiated using specific binding operators like GOAL, CONDITION and CAUSE.

Format of NKRL Templates: Templates take the form of n -ary combinations of quadruples connecting together the ‘symbolic name’ of the template, a ‘conceptual predicate’ and the ‘arguments’ of the predicate introduced by named relations, the ‘roles’ (like SUBJ(ect), OBJ(ect), SOURCE, BEN(e)F(iciary), etc.). The quadruples have in common the ‘name’ and ‘predicate’ components. Denoting then with L_i the symbolic label identifying the template, with P_j the predicate, with R_k the generic

role and with a_k the generic argument, the core data structure for templates has the format:

$$(L_i (P_j (R_1 a_1) (R_2 a_2) \dots (R_n a_n))) .$$

Templates are included in an inheritance hierarchy, HTemp(ates), which implements NKRL’s ‘ontology of events’.

NKRL Inference Engine: A software module that carries out the different ‘reasoning steps’ included in hypotheses or transformations. It allows us to use these two classes of inference rules also in an ‘integrated’ mode, augmenting then the possibility of finding interesting (implicit) information.

NKRL Inference Rules, Hypotheses: They are used to build up automatically ‘reasonable’ connections among the information stored in an NKRL knowledge base according to a number of pre-defined reasoning schemata, e.g., ‘causal’ schemata’.

NKRL Inference Rules, Transformations: These rules try to ‘adapt’, from a semantic point of view, a query that failed to the contents of the existing knowledge bases. The principle employed consists in using rules to automatically ‘transform’ the original query into one or more different queries that are not strictly ‘equivalent’ but only ‘semantically close’ to the original one.

Ontology of Concepts vs. Ontology of Events: The ontologies of concepts concern the ‘standard’ hierarchical organizations of concepts to be used to model (in a ‘static’ way) a given domain. NKRL adds an ‘ontology of events’, i.e., a new sort of hierarchical organization where the nodes, represented by n -ary structures called ‘templates’, represent general classes of ‘dynamical’ events like “move a physical object”, “produce a service”, “send/receive a message”, etc.

“Narrative” Information Problems

Gian Piero Zarri

LaLIC, University Paris 4-Sorbonne, France

INTRODUCTION

‘Narrative’ information concerns in general the account of some real-life or fictional story (a ‘narrative’) involving concrete or imaginary ‘personages’. In this article we deal with (*multimedia*) *nonfictional narratives of an economic interest*. This means, first, that we are not concerned with all sorts of *fictional* narratives that have mainly an entertainment value, and represent an imaginary narrator’s account of a story that happened in an imaginary world: a novel is a typical example of fictional narrative. Secondly, our ‘nonfictional narratives’ must have an *economic value*: they are then typically embodied into corporate memory documents, they concern news stories, normative and legal texts, medical records, intelligence messages, surveillance videos or visitor logs, actuality photos and video fragments for newspapers and magazines, eLearning and multimedia Cultural Heritage material, etc.

Because of the ubiquity of these ‘narrative’, ‘dynamic’ resources, it is particularly important to build up *computer-based applications* able to represent and to exploit in a general, accurate, and effective way the *semantic content* – i.e., the key ‘meaning’ – of these resources.

BACKGROUND

‘Narratives’ represent presently a very ‘hot’ domain. From a *theoretical point of view*, they constitute the object of a full discipline, the ‘narratology’, whose aim can be defined as that of producing an *in-depth description of the ‘syntactic/semantic structures’ of the narratives*, i.e., the narratologist is in charge of dissecting narratives into their component parts in order to establish their functions, their purposes and the relationships among them. A good introduction to the full domain is (Jahn, 2005).

Even if narratology is particularly concerned with *literary analysis* (and, therefore, with ‘fictional’ narra-

tives), these last years some of its varieties have acquired a particular importance also from a strict Artificial Intelligence (AI) and Computer Science (CS) point of view. Leaving apart the old dream of generating fictions by computer, see (Mehan, 1977) and, more recently, (Callaway and Lester, 2002), we can mention here two new disciplines, ‘storytelling’ and ‘eChronicles’, that are of interest from both a nonfictional narratives and a AI/CS point of view.

Storytelling – see, e.g., (Soulier, 2006) – concerns in general the study of the different ways of *conveying ‘stories’ and events in words, images and sounds* in order to entertain, teach, explain etc. *Digital Storytelling* deals in particular with the ways of introducing characters and emotions in the *interactive entertainment domain*, and concerns then videogames, massively multiplayer online games, interactive TV, virtual reality etc., see (Handler Miller, 2004). Digital Storytelling is, therefore, related to another, computer-based variant of narratology called *Narrative Intelligence*, a sub-domain of AI that *explores topics at the intersection of Artificial Intelligence, media studies, and human computer interaction design* (narrative interfaces, history databases management systems, artificial agents with narrative structured behaviour, systems for the generation and/or understanding of histories/narratives etc.), see (Mateas and Sengers, 2003).

An *eChronicle system* can be defined in short as way of *recording, organizing and then accessing streams of multimedia events captured by individuals, groups, or organizations making use of video, audio and other sensors*. The ‘chronicles’ gathered in this way may concern any sort of ‘narratives’ from meeting minutes to football games, sales activities, ‘lifelogs’ obtained from wearable sensors, etc. The technical challenges concern mainly the ways of aggregating the events into coherent ‘episodes’ making use of domain models as ontologies, and providing then access to this sort of material to the users at the required level of granularity. Note that *exploration, and not ‘normal’ querying, is the predominant way of interaction with the chronicle*

repositories; more details can be found, e.g., in (Güven, Podlaseck and Pingali, 2005), (Westermann and Jain, 2006).

The solution (NKRL) proposed for the ‘intelligent’ management of nonfictional narratives in the companion article – ‘Narrative’ Information, the NKRL Solution – of the present one is considered as a fully-fledged eChronicle technique, see (Zarri, 2006). In NKRL, however, a fundamental aspect concerns the presence of powerful ‘*reasoning*’ techniques – an aspect that is not taken into consideration sufficiently in depth in eChronicles that are mainly interested in the accumulation of narrative materials more than in the ‘intelligent’ exploitation of their inner relationships.

REPRESENTING THE ‘NONFICTIONAL’ NARRATIVES

All the different sorts of ‘nonfictional narratives’ evoked in the previous Sections concern, practically, the *description of spatially and temporally characterised ‘events’ that relate, at some level of abstraction, the behaviour or the state of some real-life ‘actors’* (characters, personages, etc.): these try to attain a specific result, experience particular situations, manipulate some (concrete or abstract) materials, send or receive messages, buy, sell, deliver etc. Note that:

- The term ‘event’ is taken here in its *most general meaning*, covering also strictly related notions like fact, action, state, situation, episode, activity etc.
- The ‘actors’ or ‘personages’ involved in the events *are not necessarily human beings*: we can have narratives concerning, e.g., the vicissitudes in the journey of a nuclear submarine (the ‘actor’, ‘subject’ or ‘personage’) or the various avatars in the life of a commercial product.
- Even if a large amount of nonfictional narratives are embodied within natural language (NL) texts, this is *not necessarily true*: narrative information is really ‘*multimedia*’. A photo representing a situation that, verbalized, could be expressed as “The US President is addressing the Congress” is not of course an NL document, yet it surely represents a narrative.

An in-depth analysis of the existing Knowledge Representation solutions that *could* be used to represent and manage nonfictional narratives endowed with the above characteristics is beyond the possibilities of this article – see in this context, e.g., (Zarri, 2005). We will limit ourselves, here, to some quick consideration.

We can note, first of all, that the now so popular Semantic Web (W3C) languages like RDF (Resource Description Framework), see (Manola and Miller, 2004), and OWL (Web Ontology Language), see (McGuinness and Harmelen, 2004) are unable to fit the bill because their core formalism consists in practice of the classical ‘*attribute – value*’ model. For these ‘binary’ languages then, a property can only be a *binary relationship*, linking two individuals or an individual and a value. When these languages must represent simple ‘narratives’ like “John has given a book to Mary”, several difficulties arise. In this extremely simple sentence, e.g., “give” is an *n-ary (ternary) relationship* that, to be represented in a complete way, asks for the presence of a specific ‘*semantic predicate*’ in the “give” or “transfer” style, where the ‘*arguments*’, “John”, “book” and “Mary”, of the predicate must be labelled with ‘*conceptual roles*’ such as, e.g., ‘agent of give’, ‘object of give’ and ‘beneficiary of give’ respectively.

Efforts for extending the W3C languages by introducing some *n-ary* feature have been not very successful until now: see, in this context, a recent working paper from the W3C Semantic Web Best Practices and Deployment Working Group (SWBPD WG) about “Defining N-ary Relations on the Semantic Web” (Noy and Rector, 2006). This paper proposes some extensions to the binary paradigm to allow the correct representation of ‘narratives’ like: “Steve has temperature, which is high, but failing” or “United Airlines flight 3177 visits the following airports: LAX, DFW, and JFK”. The technical solutions expounded in this paper are not very convincing and have aroused several criticisms. These have focused, mainly, on i) the fact that the majority of the solutions proposed *do not deal, in reality, with the n-ary problem*, but with (only loosely) related matters like the possibility of specifying a ‘*standard*’ *binary relationship* via the addition of properties, and ii) on the *arbitrary introduction, through reification processes, of fictitious (and inevitably ad hoc) ‘individuals’ to represent the n-ary relations* when these are actually dealt with. Moreover, the paper say nothing,

e.g., about the way of dealing, in concrete ‘narrative’ situations, with those crucial ‘*connectivity phenomena*’ like causality, goal, indirect speech, co-ordination and subordination etc. that *link together the basic pieces of information* – e.g., the ‘basic events’ corresponding to the present illness state of Steve with other ‘basic events’ corresponding to the (possible or definite) ‘causes’ of such state.

Several solutions for representing narratives in computer-usable ways according to some sort of *actual* ‘*n*-ary model’ have been described in the literature. For example, in the context of his work – between the mid-fifties and the mid-sixties – on the set up of a mechanical translation process based on the simulation of the thought processes of the translator, Silvio Ceccato (Ceccato, 1961) proposed a representation of narrative-like sentences as a network of *triadic structures* (‘correlations’) organized around specific ‘correlators’ (a sort of roles). Ceccato is also credited to be one of the pioneers of the semantic network studies; basically, semantic networks are directed graphs (digraphs) where the nodes represent concepts, and the arcs different kinds of associative links, not only the ‘classical’ IsA and property-value links, but also *n*-ary relationships. A panorama of the different conceptual solutions proposed in a semantic network context can be found in (Lehmann, 1992).

In the seventies, a sort of particularly popular, *n*-ary semantic network approach has been represented by the Conceptual Dependency theory of Roger Schank (Schank, 1973). In this theory, the underlying meaning (‘conceptualization’) of narrative-like utterances is expressed as *combinations of ‘semantic predicates’* chosen from a set of twelve ‘primitive actions’ (like INGEST, MOVE, ATRANS, the transfer of an abstract relationship like possession, ownership and control, PTRANS, physical transfer, etc.) plus states and changes of states, and *seven role relationships* (‘*conceptual case*’). Conceptual Graphs (CGs) is the representation system developed by John Sowa (Sowa, 1984, 1999) and derived, at least partly, from Schank’s work and other early work in the Semantic Networks domain. CGs make use of a *graph-based notation* for representing ‘concept-types’ (organized into a type-hierarchy), ‘concepts’ (that are instantiations of concept types) and ‘conceptual relations’ that relate one concept to another. CGs can be used to represent in a formal way narratives like “A pretty lady is dancing gracefully” and more complex,

second-order constructions like contexts, wishes and beliefs. CYC, see (Lenat *et al.*, 1990) concerns one of the most controversial endeavours in the history of Artificial Intelligence. Started in the early ‘80 as a MCC (Microelectronics and Computer Technology Corporation, Texas, USA) project, it ended about 15 years later with the set up of an *enormous knowledge base* containing about a million of hand-entered ‘logical assertions’ including both simple statements of facts and rules about what conclusions can be inferred if certain statements of facts are satisfied. The ‘upper level’ of the ontology that structures the CYC knowledge base is now freely accessible on the Web, see <http://www.cyc.com/cyc/opencyc>. A detailed analysis of the origins, developments and motivations of CYC can be found in (Bertino *et al.*, 2001: 275-316). We can also mention here another ‘modern’ system, Topic Maps, see (Rath, 2003), where information is represented using topics (representing any concept, from people to software modules and events), associations (the relationships between them), and occurrences (the relationships between topics and information resources relevant to them). They correspond, eventually, to a sort of down-graded Semantic Network representation.

Leaving now aside ‘historical’ solutions like those proposed by Schank or Ceccato, *none of the existing n-ary solutions mentioned above seem to be able to satisfy completely the nonfictional narratives requirements*, see again (Zarri, 2005) for more details. The universal purposes of CYC, the extremely large dimensions of its knowledge base and the extreme diversity of the contents of this base give rise to *serious consistency problems*, that have apparently restricted the development of concrete applications based on this technology to experimental projects mainly supported by the US Government. On the other hand, the knowledge representation language of CYC, CycL (substantially, a frame system rewritten in logical form) seems to be *too rigid and uniform* to adapt itself to the representation of all the different facets (from general concepts and elementary events to the connectivity phenomena etc.) that characterise the narratives. Conceptual Graphs (CGs) could represent, at least in principle, a valid solution for dealing with nonfictional narrative information. However, it seems evident that work in a CGs context concerns mainly, with few exceptions, the ‘academic’ domain, and that the practically-oriented applications of CGs are particularly scarce. This becomes particular

evident when we consider that the CGs developers *still lack of an exhaustive and authoritative list of standard CGs structures under the form of 'canonical graphs'* that could constitute a sort of 'catalogue' for dealing with practical problems; the set up of a tool like this seems never have been planned. The existence of such a catalogue could be extremely important for practical applications in the narrative (not only) domain given that: i) a system-builder should not have to create himself the structural and inferential knowledge needed to describe and exploit the events proper to a (sufficiently) large class of narratives; ii) the reproduction and the sharing of previous results could become neatly easier.

We can add to the above difficulties the existence of a series of *general problems* that are not associated with a specific system but that concern by and large all the existing *n*-ary solutions, like the lack of agreement about the list of 'roles' (conceptual cases) to be used when a narrative must be practically represented into conceptual format, or the differences of opinion about the use of 'primitives'.

ACTUAL TRENDS

In spite of the quite pessimistic considerations of the previous Section, conceiving a *specific Knowledge Representation tool* for dealing in practice with nonfictional narrative information is far from being impossible. Returning now to the "John gave a book..." example above – and leaving aside, for the moment being, all the additional problems linked, e.g., with the existence of the 'connectivity phenomena' – it is not too difficult to see that a complete, *n*-ary representation that captures all the '*essential meaning*' of this elementary narrative amounts to:

- Define JOHN_, MARY_ and BOOK_1 as 'individuals', instances of general 'concepts' like human_being and information_support or of more specific concepts. Concepts and instances (individuals) are, as usual, collected into a 'binary' ontology (built up using a standard tool like, e.g., Protégé).
- Define an *n*-ary structure organised around a *conceptual predicate* like, e.g., MOVE or PHYSICAL_TRANSFER and associate the above individuals (the arguments) to the predicate through the use of *conceptual roles* that specify their

'function' within the global narrative. JOHN_ will then be introduced by an AGENT (or SUBJECT) role, BOOK_1 by an OBJECT (or PATIENT) role, MARY_ by a BENEFICIARY role. An additional information like "yesterday" could be introduced by, e.g., a TEMPORAL_ANCHOR role, etc.

- 'Reify' the obtained *n*-ary structured associating with it an *unique identifier* under the form of a 'semantic label', to assure both i) the logical-semantic coherence of the structure; ii) an rational and efficient way of storing and retrieving it.

Formally, an *n*-ary structure defined according the above guidelines can be described as:

$$(L_i (P_j (R_1 a_1) (R_2 a_2) \dots (R_n a_n))) \quad (1)$$

where L_i is the symbolic label identifying the particular *n*-ary structure (e.g., the global structure corresponding to the representation of the "John gave a book..." example), P_j is the conceptual predicate, R_k is the generic role and a_k the corresponding argument (e.g., the individuals john_, mary_ etc.). Note that each of the $(R_i a_i)$ cells of (1), *taken individually*, represents a binary relationship in the W3C language style. The main point here is, however, that the whole conceptual structure represented by (1) must be considered *globally*.

The solution represented formally by (1) is at the core of a complete and running conceptual tools for the representation and management of nonfictional narrative information called NKRL (Narrative Knowledge representation Language), see (Zarri, 2005) and the companion article: 'Narrative' Information, the NKRL Solution.

CONCLUSION

We deal in this article with 'nonfictional narratives'. These are information resources of a high economical importance that concern, e.g., the 'corporate knowledge' documents, the news stories, the medical records, the surveillance videos or visitor logs, etc. When we examine the existing (or past) *general Knowledge Representation* systems that could be used for dealing with nonfictional narratives, we can note that none of them seem to be able to satisfy completely the non-fictional narratives requirements. For example, the

W3C (Semantic Web) languages like RDF and OWL cannot fit the bill since they are binary-based types of representation while narratives ask, in general, for n -ary solutions. A specific, narrative-oriented formalism able to capture the essential ‘meaning’ of an ‘elementary’ narrative event however exists, see (Zarri, 2005) and the companion article: ‘Narrative’ Information, the NKRL Solution.

KEY TERMS

'Binary' Languages vs. n -ary Languages: Binary languages (like RDF and OWL) are based on the classical 'attribute – value' model: they are called 'binary' because, for them, a property can only be a binary relationship, linking two individuals or an individual and a value. They cannot be used to represent in an accurate way the narratives that ask in general, on the contrary, for the use of n -ary knowledge representation languages.

Connectivity Phenomena: In the presence of several, logically linked elementary events, this term denotes the existence of a global 'narrative' information content that goes beyond the simple addition of the information conveyed by the single events. The connectivity phenomena are linked with the presence of logico-semantic relationships like causality, goal, co-ordination and subordination etc.

Core Format of a Complete Solution for Representing Narratives: Formally, an n -ary structure able to represent the 'essential meaning' of an 'elementary event' can be described as:

$$(L_i (P_j (R_1 a_1) (R_2 a_2) \dots (R_n a_n)))$$

where L_i is the symbolic label identifying the particular formalized event, P_j is the conceptual predicate, R_k is the generic role and a_k the corresponding argument.

Examples of n -ary Languages: 'Historical' examples of n -ary languages are Ceccato's 'correlations', Schank's Conceptual Dependency theory, many Semantic Networks proposals, etc. Current n -ary systems are, e.g., Topic Maps, Sowa's Conceptual Graphs, Lenat's CYC, etc. None of them are able to satisfy completely the requirements for an 'intelligent' representation and management of nonfictional narrative information.

Narrative Information: Concerns in general the account of some real-life or fictional story (a 'narrative') involving concrete or imaginary 'personages'.

Narratology: Discipline that deals with narratives from a theoretical point of view. Sub-classes of narratology that have a 'computational' interest are, e.g., Storytelling, Narrative Intelligence and the eChronicle systems.

Nonfictional Narrative of an Economic Interest: In this case, the personages are 'real characters', and the narrative happens in the real world. Moreover, the narratives are now embodied in multimedia documents of an economic interest: corporate memory documents, news stories, normative and legal texts, medical records, intelligence messages, surveillance videos or visitor logs, etc.

Natural Language Processing and Biological Methods

Gemma Bel Enguix

M. Dolores Jiménez López

Rovira i Virgili University, Spain

INTRODUCTION

During the 20th century, biology—especially molecular biology—has become a pilot science, so that many disciplines have formulated their theories under models taken from biology. Computer science has become almost a bio-inspired field thanks to the great development of natural computing and DNA computing.

From linguistics, interactions with biology have not been frequent during the 20th century. Nevertheless, because of the “linguistic” consideration of the genetic code, molecular biology has taken several models from formal language theory in order to explain the structure and working of DNA. Such attempts have been focused in the design of grammar-based approaches to define a combinatorics in protein and DNA sequences (Searls, 1993). Also linguistics of natural language has made some contributions in this field by means of Collado (1989), who applied generativist approaches to the analysis of the genetic code.

On the other hand, and only from theoretical interest a strictly, several attempts of establishing structural parallelisms between DNA sequences and verbal language have been performed (Jakobson, 1973, Marcus, 1998, Ji, 2002). However, there is a lack of theory on the attempt of explaining the structure of human language from the results of the semiosis of the genetic code. And this is probably the only arrow that remains incomplete in order to close the path between computer science, molecular biology, biosemiotics and linguistics.

Natural Language Processing (NLP)—a subfield of Artificial Intelligence that concerns the automated generation and understanding of natural languages—can take great advantage of the structural and “semantic” similarities between those codes. Specifically, taking the systemic code units and methods of combination of the genetic code, the methods of such entity can be translated to the study of natural language. Therefore, NLP could become another “bio-inspired” science, by

means of theoretical computer science, that provides the theoretical tools and formalizations which are necessary for approaching such exchange of methodology.

In this way, we obtain a theoretical framework where biology, NLP and computer science exchange methods and interact, thanks to the semiotic parallelism between the genetic code and natural language.

BACKGROUND

Most current natural language approaches show several facts that somehow invite to the search of new formalisms to account in a simpler and more natural way for natural languages. Two main facts lead us to look for a more natural computational system to give a formal account of natural languages: a) natural language sentences cannot be placed in any of the families of the Chomsky hierarchy (Chomsky, 1956) in which current computational models are basically based, and b) rewriting methods used in a large number of natural language approaches seem to be not very adequate, from a cognitive perspective, to account for the processing of language.

Now, if to these we add (1) that languages that have been generated following a molecular computational model are placed in-between Context-Sensitive and Context-Free families; (2) that genetic model offers simpler alternatives to the rewriting rules; (3) and that genetics is a natural informational system as natural language is, we have the ideal scene to propose biological models in NLP.

The idea of using biological methods in the description and processing of natural languages is backed up by a long tradition of interchanging methods in biology and natural/formal language theory:

1. **Results and methods in the field of formal language theory have been applied to biology:**

- (1) Pawlak (1965) dependency grammars as an approach in the study of protein formation; (2) transformational grammars for modeling gene regulations (Collado, 1989); (3) stochastic context-free grammars for modeling RNA (Sakakibara et al., 1994); (4) definite clause grammars and cut grammars to investigate gene structure and mutations and rearrangement in it (Searls, 1989); (5) tree-adjointing grammars for predicting RNA structure of biological data (Uemura et al., 1999).
2. **Natural languages as models for biology:** (1) Watson (1968) understanding of heredity as a form of communication; (2) Asimov (1968) idea that nucleotide bases are letters and they form an alphabet; (3) Jacob (1970) consideration that the sense of the genetic message is given by the combination of its signs in words and by the arrangement of words in phrases; (4) Jakobson (1970) ideas about taking the nucleotide bases as phonemes of the genetic code or about the binary oppositions in phonemes and in the nucleic code.
3. **Biological ideas in linguistics:** (1) the “tree model” proposed by Schleicher (1863); (2) the “wave model” due to Schmidt (1872); (3) the “geometric network model” proposed by Forster (1997); or (3) the naturalistic metaphor in Linguistics defended by Jakobson (1970, 1973).
4. **Using DNA as a support for computation** is the basic idea of Molecular Computing (Păun et al., 1998). Speculations about this possibility can be found in Feynman (1961), Bennett (1973) and Conrad (1995).

BIOLOGICAL METHODS IN NLP

Here, we present an overview of different bio-inspired methods that during the last years have been successfully applied to several NLP issues, from syntax to pragmatics. Those methods are taken mainly from computer science and are basically the following: *DNA computing, membrane computing and networks of evolutionary processors*.

DNA Computing

One of the most developed lines of research in natural computing is the named molecular computing, a model based on molecular biology, which arose mainly after Adleman (1994). An active area in molecular computing is DNA computing (Păun et al., 1998) inspired in the way that DNA perform operations to generate, replicate or change the configuration of the strings.

Application of molecular computing methods to natural language syntax gives rise to **molecular syntax** (Bel-Enguix & Jiménez-López, 2005a). Molecular syntax takes as a model two types of mechanisms used in biology in order to modify or generate DNA sequences: *mutations* and *splicing*. Mutations refer to changes performed in a linguistic string, being this a phrase, sentence or text. Splicing is a process carried out involving two or more linguistic sequences. It is a good framework for approaching syntax, both from the sentential or dialogical perspective.

Methods used by molecular syntax are based on basic genetic processes: *cut, paste, delete* and *move*. Combining these elementary rules most of the complex structures of natural language can be obtained, with a high degree of *simplicity*.

This approach is a test of the generative power of splicing for syntax. It seems, according to the results achieved, that splicing is quite powerful for generating, in a very simple way, most of the patterns of the traditional syntax. Moreover, the new perspectives and results it provides, could mean a transformation in the general perspective of syntax.

From here, we think that bio-NLP, applied in a methodological and clear way, is a powerful and simple model that can be very useful to a) formulate some systems capable of generating the larger part of structures of language, and b) define a formalization that can be implemented and may be able to describe and predict the behavior of natural language structures.

Membrane Computing

Membrane Systems (MS) (Păun, 2000) are models of computation inspired by some basic features of biological membranes. They can be viewed as a new paradigm in the field of natural computing based on the functioning of membranes inside the cell. MS can be used as generative, computing or decidability devices. This new computing model has several intrinsically

interesting features such as, for example, the use of multisets and the inherent parallelism in its evolution and the possibility of devising computations which can solve exponential problems in polynomial time.

This framework provides a powerful tool for formalizing any kind of interaction, both among agents and among agents and environment. One of key ideas of MS is that generation is made by evolution. Therefore, most of evolving systems can be formalized by means of membrane systems.

Linguistic Membrane Systems (LMS) (Bel-Enguix & Jiménez-López, 2005b) aim to model linguistic processes, taking advantage of the flexibility of MS and their suitability for dealing with some fields where contexts are a central part of the theory. LMS can be easily adapted to deal with different aspects of the description and processing of natural languages. The most developed applications of LMS are *semantics* and *dialogue*.

MS are a good framework for developing a semantic theory because they are evolving systems by definition, in the same sense that we take meaning to be a dynamic entity. Moreover, MS provide a model in which contexts, either isolated or interacting, are an important element which is already formalized and can give us the theoretical tools we need. Semantic membranes may be seen as an integrative approach to semantics coming from formal languages, biology and linguistics. Taking into account results obtained in the field of computer science as well as the naturalness and simplicity of the formalism, it seems the formalization of contexts by means of membranes is a promising area of research for the future. Examples of application of MS to semantics can be found in Bel-Enguix and Jiménez-López (2007).

A topic where context and interaction among agents is essential is the field of dialogue modeling and its applications to the design of effective and user-friendly computer dialogue systems. Taking into account a pragmatic perspective of dialogue and based on speech acts, multi-agent theory and dialogue games, Dialogue Membrane Systems have arisen, as an attempt to compute speech acts by means of MS. Considering membranes as agents, and domains as a personal background and linguistic competence, the application to dialogue is almost natural, and simple from the formal point of view. For examples of this application see Bel-Enguix and Jiménez-López (2006b).

NEPS-Networks of Evolutionary Processors

Networks of Evolutionary Processors (NEPs) are a new computing mechanism directly inspired in the behavior of cell populations. Every cell is described by a set of words (DNA) evolving by mutations, which are represented by operations on these words. At the end of the process, only the cells with correct strings will survive. In spite of the biological inspiration, the architecture of the system is directly related to the Connection Machine (Hillis, 1985) and the Logic Flow paradigm (Errico et al. 1994). Moreover, the global framework for the development of NEPs has to be completed with the biological background of DNA computing (Păun et al., 1998), membrane computing (Păun, 2000) and, specially, with grammar systems (Csuhaaj-Varjú et al., 1994), which share with NEPs the idea of several devices working together and exchanging results.

First precedents of NEPs as generating devices can be found in Csuhaaj-Varjú & Salomaa (1997) and Csuhaaj-Varjú & Mitrana (2000). The topic was introduced in Castellanos et al. (2003) and Martín-Vide et al. (2003), and further developed in Castellanos et al. (2005), Csuhaaj-Varjú et al. (2005).

With this background and theoretical connections, it is easy to understand how NEPs can be described as agential bio-inspired context-sensitive systems. Many disciplines are needed of these types of models that are able to support a biological framework in a collaborative environment. The conjunction of these features allows applying the system to a number of areas, beyond generation and recognition in formal language theory. NLP is one of the fields with a lack of biological models and with a clear suitability for agential approaches.

NEPs have significant intrinsic multi-agent capabilities together with the environmental adaptability that is typical of bio-inspired models. Some of the characteristics of NEPs architecture are the following: *Modularization*, *contextualization* and *redefinition* of agent capabilities, *synchronization*, *evolvability* and *learnability*.

Inside of the construct, every agent is *autonomous*, *specialized*, *context-interactive* and *learning-capable*.

In what refers to the functioning of NEPs, two main features deserve to be highlighted: *emergence* and *parallelism*.

Because of those features, NEPs seems to be a suitable model for tackling natural languages. One of the main problems of natural language is that it is generated in the brain, and there is a lack of knowledge of the mental processes the mind undergoes to bring about a sentence. While expecting new advances in neuro-science, we have to use models that seem to fit better to NLP. Modularity has shown to be an important idea in a wide range of fields: cognitive science, computer science and, of course, NLP. NEPs provide a suitable theoretical framework for formalization of modularity in NLP.

Another chief problem for the formalization and processing of natural language is its changing nature. Not only words, but also rules, meaning and phonemes can take different shapes during the process of computation. Formal models based in mathematical language have a lack of flexibility to describe natural language. Biological models seem to be better to this task, since biological entities share with languages the concept of “evolution”. From this perspective, NEPs offer enough flexibility to model any change at any moment in any part of the system. Besides, as a bio-inspired method of computation, they have the capability of simulating natural evolution in a highly pertinent and specialized way.

Some linguistic disciplines, as pragmatics or semantics, are context-driven areas, where the same utterance has different meanings in different contexts. To model such variation, a system with a good definition of environment is needed. NEPs offer some kind of solution to approach formal semantics and formal pragmatics from a natural computing perspective.

Finally, the multimodal approach to communication, where not just production, but also gestures, vision and supra-segmental features of sounds have to be tackled, refers to a parallel way of processing. NEPs allow modules to work in parallel. The autonomy of every one of the processors and the possible miscoordination between them can also give account of several problems of speech.

Examples of NEPs applications to NLP can be found in Bel-Enguix and Jiménez-López (2005c, 2006a).

FUTURE TRENDS

Three general formalisms for dealing with NLP by means of biological methods have been introduced,

focusing on the formal definition of several frameworks that adapt models coming from the area of bio-inspired computation to NLP needs. The main trends for the future focus on the implementation of these models in order to test their computational advantages over classical models of NLP without biological inspiration.

CONCLUSION

The coincidences between several structures of language and biology allow us, in the field of NLP, to take advantage of the bio-inspired models formalized by theoretical computer science. Moreover, the multi-agent capabilities of some of these models make them a suitable tool for simulating the processes of generation and recognition in natural language.

Biological methods coming from computer science can be very useful in the field of natural language, since they provide simple, flexible and intuitive tools for describing natural languages and making easier their implementation in NLP systems.

This research provides an integrative path for biology, computer science and NLP – three branches of human knowledge that have to be together in the development of new systems of communication for future global society.

KEY TERMS

Grammar Systems Theory: A consolidated and active branch in the field of formal languages that provides syntactic models for describing multi-agent systems at the symbolic level using tools from formal languages and grammars.

Membrane Systems: In a membrane system multi-sets of objects are placed in the compartments defined by the membrane structure that delimits the system from its environment. Each membrane identifies a *region*, the space between it and all directly inner membranes. Objects evolve by means of reaction rules associated with compartments, and applied in a maximally parallel, nondeterministic manner. Objects can pass through membranes, membranes can change their permeability, dissolve and divide.

Multi-Agent System: A system composed of a set of computational agents that perform local problem solving and cooperatively interact to solve a single problem (or reach a goal) difficult to be solve (achieved) by an individual agent.

Mutations: Several types of transformations in a single string.

Natural Computing: Research field that deals with computational techniques inspired by nature and natural systems. This type of computing includes evolutionary algorithms, neural networks, molecular computing and quantum computing.

Neural Network: Interconnected group of artificial neurons that uses a mathematical or a computational model for information processing based on a connectionist approach to computation. It involves a network of simple processing elements that can exhibit complex global behaviour.

Splicing: Operation which consists of splitting up two strings in an arbitrary way and sticking the left side of the first one to the right side of the second one (direct splicing), and the left side of the second one to the right side of the first one (inverse splicing).

Natural Language Understanding and Assessment

INTRODUCTION

Natural language understanding and assessment is a subset of natural language processing (NLP). The primary purpose of natural language understanding algorithms is to convert written or spoken human language into representations that can be manipulated by computer programs. Complex learning environments such as intelligent tutoring systems (ITSs) often depend on natural language understanding for fast and accurate interpretation of human language so that the system can respond intelligently in natural language. These ITSs function by interpreting the meaning of student input, assessing the extent to which it manifests learning, and generating suitable feedback to the learner. To operate effectively, systems need to be fast enough to operate in the real time environments of ITSs. Delays in feedback caused by computational processing run the risk of frustrating the user and leading to lower engagement with the system. At the same time, the accuracy of assessing student input is critical because inaccurate feedback can potentially compromise learning and lower the student's motivation and metacognitive awareness of the learning goals of the system (Millis et al., 2007). As such, student input in ITSs requires an assessment approach that is fast enough to operate in real time but accurate enough to provide appropriate evaluation.

One of the ways in which ITSs with natural language understanding verify student input is through *matching*. In some cases, the match is between the user input and a pre-selected *stored answer to a question*, *solution to a problem*, *misconception*, or other form of
